WILLIAMS, TOM A., M.B.
WOODBURY, WILLIAM R., M.D.

INDEX TO VOLUME CLXIII.

AUTHORS.

Adler, Herman M. Some effects of overfeeding with fats in certain cases of insanity, 225.
Alford, L. B. Ten obscure cases of mental disease: a clinical and anatomical study, 182.
Allen, Freeman. Spinal anesthesia, 715.
Austin, A. E., Ordway, Mabel, Montague, Ruth. On the absorption of protein and fat in pulmonary tuberculosis, 575.
Ayer, James B. An analysis of seventy-two cases of pneumothorax, 501.

Balch, F. G., Smith, G. G. Twenty-one cases of acute pancreatitis, 384.
Barney, J. Dellinger. The care and management of the tabetic bladder. I. Diagnosis, 933; II. Etiology, 985.
Boardman, William P. Further observations on the Wassermann reaction for syphilis, 641.
Bradford, E. H., Soutter, Robert. Scoliosis, 570.
Brewer, Isaac W. Tuberculosis amongst the Philippine scouts (native troops) of the United States army, 940.
Brown, Gordon T. The diagnosis of fractured skull as aided by the finding of brain tissue in the vomitus, 220.
Burns, Newell B. Note concerning brain and other visceral weights in sixty-six subjects showing carcinoma, 222.

Cabot, Hugh, Dodd, W. J. The diagnosis of stone in the pelvic portion of the ureter. A preliminary report on certain limitations of radiographic diagnosis and a suggested remedy, 85.
Cabot, Hugh. The value of tuberculin in tuberculosis of the urinary tract, 471; remarks on the technic of operations for stone in the ureter, 789; a case of myxo-fibro-sarcoma originating in the great omentum with involvement of the bladder and small intestine, 841.
Canavan, Myrtelle M. Bacillary dysentery at the Danvers State Hospital, Massachusetts, subsequent to the epidemic of 1908 (December, 1908–June, 1910), 209; organisms recovered from dysentery cases studied bacteriologically, December, 1908–June, 1910, Danvers State Hospital, Massachusetts, 211; mannite and non-mannite-fermenting organisms in a case of dysentery, complicated by hemorrhagic endometritis probably due to a third organism, 212; the persistence of agglutinins for B. dysenteriæ in Danvers Hospital cases, together with a series of conglutination tests, 212.
Canavan, Myrtelle M., Southard, E. E. Bacterial invasion of the blood and the cerebrospinal fluid by way of mesenteric lymph nodes: a study of fifty cases of mental disease, 202.
Chase, Richard F. Cholelithiasis, 639.
Chute, Arthur L. The small fibrous prostate, 606.
Clark, J. Payson. Two unusual cases of disease of the maxillary antrum, 395.
Clark, W. Irving. The etiology of cholecystic gallstones, 675.
Cobb, Carolus M. The necessity of the general practice of medicine as a preliminary training for those engaged in special work, 361.
Coolidge, A., Jr. The etiology of common colds, 58.
Coriat, Isador H. A case resembling myotonia occurring in an adult, due to the trichina spiralis, with the pathological findings in the muscles, 992.
Cornwall, Andrew P., Painter, Charles F. The technic of arthrotomy. A report upon and discussion of one hundred and ninety-eight cases, 601, 645, 688, 723, 760, 797.
Couse, William Pearce. Two cases of transverse subperiosteal fracture of the lower end of the radius in children, 364.
Crile, G. W. Phylogenetic association in relation to certain medical problems, 893.
Cumston, Charles Greene. An historical notice of the operation of Cæsarean section from the first operation to the middle of the eighteenth century, 316; spontaneous dislocation of the hip-joint following acute infectious diseases, 684; a biography of Charles Spon, M.D., 990.

DePaoli, E. Clinical and bacteriological researches on Mikulicz's method of rendering the peritoneum resistant to surgical infections, 759.
Dodd, W. J., Cabot, Hugh. The diagnosis of stone in the pelvic portion of the ureter. A preliminary report on certain limitations of radiographic diagnosis and a suggested remedy, 85.
Dodd, Walter L., Orton, Samuel T. Experiments on transmission of bacteria by flies with special relation to an epidemic of bacillary dysentery at the Worcester State Hospital, Massachusetts, 1910, 863.
Donley, John E. A fallacy of psychotherapy. "Fighting it out" in functional nervous disorders, 679.

Eastman, Theodore Jewett, Jackson, James Marsh. The present status of the treatment of exophthalmic goiter, 419.
Emerson, Francis P. Individual efficiency, 17.
Emerson, William R. P. The hygienic and dietetic treatment of delicate children by the class method (abstract), 326.

Foote, J. S. The comparative histology of femoral bones, 613.
Forbes, A. Mackenzie. Notes on the condition denominated external and internal atony, suggesting its association with tuberculosis, 249.

Garrish, Frederic Henry. A crusade against syphilis and gonorrhea, 1.
Gilpatrick, R. H. Suture of the faucial pillars for hemorrhage following tonsillectomy, 97.
Goldthwait, Joel E. Distortion of the face and skull due to continued fixed posture in early infancy, 429.
Goodall, Henry Skinner. Some results of sanatorium treatment of pulmonary tuberculosis in children, 432.
Graves, W. B. Indications for abdominal hysterectomy, 379; post operative pneumonia without mortality in two thousand consecutive surgical operations at the Free Hospital for Women, 497; analysis of wound infection in one thousand consecutive clean operative cases, 610; operative treatment of atresia of the vagina, 753; present knowledge of the laws of heredity, 829.
Green, Robert M. Cancer of the scrotum, 755, 792.
Griffin, Walter A. The use of tuberculin at the Sharon sanatorium, 131.

Hamilton, A. S. A study of the senile spinal cord in cases of mental disease, 189.
Hanson, Justice G. Medical inspection in public schools, 242.
Hare, C. H. An extra-uterine pregnancy at full term, 873.
Hartwell, H. F. Bacterial vaccines in pyogenic infections of the urinary tract, 472.
Hastings, R. W., Leary, Timothy. The therapeutic use of ascitic fluid. (A preliminary communication), 283.
Hawes, John B., 2d. Educational methods in the anti-tuberculosis campaign, 350; the tuberculosis problem as applied to children, 904.
Hinsdale, Guy. The meteorologic and hygienic aspects of the floods in France in 1910, 290.
Hornor, Albert A. Incidence of heart disease in acute psychoses, Danvers State Hospital, Massachusetts, 1879–1909, 200.
Howe, Oliver H. The personal relation of the physician to his patients, 358.
Hurland, C. A. Nephritis without albumen, 118.
Hubbard, Joshua C. Some observations on the surgery of the vascular system, 391.
Huntington, James Lincoln. Extraperitoneal Cæsarean section, 911.

Jackson, Henry. The clinical aspects of arteriosclerosis, 237.
Jackson, J. M., Eastman, Theodore Jewett. The present status of the treatment of exophthalmic goiter, 419.
Johnson, F. W. Ovarian cysts with twisted pedicles, 436; persistent vomiting of pregnancy, 474.

Kendall, Arthur I. Lactic acid bacteria; what they are and what they are supposed to do, 322; certain aspects of the bacteriology of bacillary dysentery, 398.
Kendall, Arthur I., Smith, Richard M. A rapid presumptive test for diarrhea caused by the gas bacillus, 578.

Lane, C. Guy. Bilharziasis; report of a case with appendicitis; literature since 1904, 937.
Leary, Timothy. Immunity with special reference to vaccine therapy, 527.
Leary, Timothy, Hastings, Robert W. The therapeutic use of ascitic fluid. (A preliminary communication), 283.
Lord, Frederick T. A contribution to the etiology of actinomycosis. The experimental production of actinomycosis in guinea pigs inoculated with the contents of carious teeth, 82.
Lothrop, Oliver A. The nasal septum; important points in anatomy and submucous resection, 128.
Lovett, Robert W. The occurrence of infantile paralysis in Massachusetts in 1909. Reported for the Massachusetts State Board of Health, 37.
Lucas, William Palmer. The diagnosis of infantile paralysis in the prodromal and early acute stage as found in the experimental study of acute poliomyelitis in monkeys, with report of findings in four human cases, 245.

Marshall, H. W. Principles underlying the study and treatment of chronic arthritis, 973.
McEvoy, George Albert. Stomach diseases from a medical standpoint, 692.
McIntosh, Herbert. The therapeutics of light, 906.
Montague, Ruth, Austin, A. E., Ordway, Mabel. On the absorption of protein and fat in pulmonary tuberculosis, 575.
Mumford, J. G. Types of Graves' disease, 532; post-operative psychoses, 838.
Myerson, Abraham. Two cases of common speech and voice defect and their treatment, 579.
Myrick, Hannah G. Some cases of sudden death during pregnancy and the puerperium, 764.

Newell, F. S. A case of hemorrhage of the newborn treated by direct transfusion; recovery, 435.
Nicols, C. C. Esophageal hemorrhage, 540.

Ordway, Mabel, Austin, A. E., Montague, Ruth. On the absorption of protein and fat in pulmonary tuberculosis, 575.
O'Reilly, Archer. Fracture of the lower epiphysis of the tibia, with a report of a case, 325.
Orton, Samuel T., Dodd, Walter L. Experiments on transmission of bacteria by flies with special relation to an epidemic of bacillary dysentery at the Worcester State Hospital, Massachusetts, 1910, 863.

Painter, Charles F. Tibiale externum and fracture of sesamoid. Report of cases, 362.
Painter, Charles F., Cornwall, Andrew P. The technic of arthrotomy. A report upon and discussion of one hundred and ninety-eight cases, 601, 645, 688, 723, 760, 797.
Peabody, A. H. An histological study of the thyroid gland in mental disease, with special reference to chronic thyroiditis, 196.
Pilcher, Paul M. Hemorrhage from the kidney, 12.
Place, Edwin H. Cutaneous diphtheria. Fatal primary case, 730.

Porter, Charles A. The surgical treatment of exophthalmic goiter 425.
Potter, Philip S. Bilious attacks in children, 55.
Powers, Charles A. Conical stump after amputation in childhood, 731.
Pratt, Joseph H. On the importance of determining the potency of digitalis preparations, 279.
Putnam, Mrs. William Lowell. Pregnancy, nursing and the care of young babies. An experiment in preventive medicine, 87.
Putnam, James J. On the etiology and treatment of the psychoneuroses, 75.

Reynolds, Edward. Gynecological operations on neurasthenics. Advantages, disadvantages, selection of cases, 113.
Richards, E. T. F. Primary adrenal tuberculosis in a case of juvenile general paresis with meningeal infection. (Bacillus coli communis), 215.
Richards, George L. A point in the technic of the use of nitrate of silver in the treatment of chronic suppurative otitis media, 402.
Ritchie, John. What medical societies can do for the health of the people, 857.
Robinson, Samuel. Acute thoracic empyema. Avoidance of chronic empyema. Rib trephining for suction drainage, 561.
Rosenau, M. J. A prophecy. Based upon studies in Pasteurization, 248.

Sanborn, George P. The place of tuberculin in the immunization of urogenital tuberculosis, 455.
Scudder, Charles L. The results of one hundred and sixty-eight operations for hernia, 343; congenital stenosis of the pylorus. The report of three successful cases following gastrojejunostomy. Remarks, 434.
Seelig, M. G. The doctrine of vitalism in medicine, 825.
Seelye, Walter C. The plastic surgery of the ovaries and tubes, 403.
Sever, James Warren. A report of the scoliosis department of the Children's Hospital, Boston, 309.
Shattuck, George Cheever. Etiology of elephantiasis, 718.
Sims, F. Robertson. A case of autochthonous sinus-thrombosis, 218.
Smith, G. G. Appendicitis during the year 1908–1909 at the Massachusetts General Hospital, 507.
Smith, G. G., Balch, F. G. Twenty-one cases of acute pancreatitis, 384.
Smith, Harold H. A case of Malta fever in Boston, 538.
Smith, R. M., Kendall, A. I. A rapid presumptive test for diarrhea caused by the gas bacillus, 578.
Smith, Theobald. What is the experimental basis for vaccine therapy? 275.
Smith, William H. A method of staining capsulated bacteria in body fluids, 791.
Southard, E. E. The laboratory work of the Danvers State Hospital, Hathorne, Massachusetts, with especial relation to the policy formulated by Dr. Charles Whitney Page, superintendent, 1888–1898, 1903–1910, 150; the margin of error in the diagnosis of mental disease, based on a clinical and anatomical review of 250 cases examined at the Danvers State Hospital, Massachusetts, 1904–1908, 155; a study of the dementia precox group in the light of certain cases showing anomalies or scleroses in particular brain regions, 150.
Southard, E. E., Canavan, Myrtelle M. Bacterial invasion of the blood and the cerebrospinal fluid by way of mesenteric lymph nodes: a study of fifty cases of mental disease, 202.
Soutter, Robert Bradford, E. H. Scoliosis, 570.
Speidel, W. C. The extreme blood picture in a case of pernicious anemia, 960.
Spooner, J. Winthrop. The shooting of Salvatore Mirando, 508.

Taft, A. E. Lesions of the major trunk viscera in epileptics, 89; report of a study of Brown-Séquard's epilepsy in the guinea pig, 868.
Tenney, Elmer S. The sputum of typhoid fever patients as a possible source of infection, 124.
Truesdale, Philemon E. Acute pancreatitis, with the report of two cases, 462.
Tyrode, M. Vejux. Drugs in practice, 121.

Webber, S. G. Congenital ophthalmoplegia externa, 721.
West, George L. The presence of air in the blood vessels in medicolegal autopsies, 327.
Wickham, Louis. Radium therapy, 982.
Williams, John T. The influence of exhaustion upon puerperal morbidity. Based upon a study of 5,000 puerperia, 468.
Williams, Tom A. A case of crossed hemidysergia and tremor, with asynergia of binocular movements: comments, 399.
Woodbury, William R. Medical social service work, 288.
Woodbury, William R., Reed, Carlisle. Hysteria with autopsy, 535.

SUBJECTS.

Abdominal Hysterectomy, indications for, W. B. Graves, M.D., 379.
Actinomycosis, a contribution to the etiology of. The experimental production of actinomycosis in guinea pigs inoculated with the contents of carious teeth, Frederick T. Lord, M.D., 82.
Agglutinins, the persistence of, for B. dysenteriæ in Danvers Hospital cases, together with a series of conglutination tests, Myrtelle M. Canavan, M.D., 218.
Air Embolism. The presence of air in the blood vessels in medico-legal autopsies, George L. West, M.D., 327.
Amputation in Childhood, conical stump after, Charles A. Powers, M.D., 731.
Anæmia, the extreme blood picture in a case of pernicious, W. C. Speidel, M.D., 650.
Anesthesia, spinal, Freeman Allen, M.D., 715.
Appendicitis during the year 1908–1909 at the Massachusetts General Hospital, G. G. Smith, M.D., 507; with bilharziasis, C. Guy Lane, 937.
Arteriosclerosis, the clinical aspects of, Henry Jackson, M.D., 237.
Arthrotomy, the technic of: a report upon and discussion of one hundred and ninety-eight cases, Charles F. Painter, M.D., and Andrew P. Cornwall, M.D., 601, 645, 688, 723, 760, 797.
Arthritis, chronic. Principles underlying the study and treatment of, H. W. Marshall, 973.
Ascitic Fluid, the therapeutic use of: a preliminary communication, Timothy Leary, M.D., and Robert W. Hastings, M.D., 283.
Atony, notes on the condition denominated external and internal, suggesting its association with tuberculosis, A. Mackenzie Forbes, M.D., 249.
Atresia of the Vagina, operative treatment of, W. P. Graves, M.D., 753.
Autochthonous Sinus-Thrombosis, a case of, F. Robertson Sims, M.D., 218.

Bacterial Vaccines in pyogenic infections of the urinary tract, H. F. Hartwell, M.D., 472.
Bilharziasis: report of a case with appendicitis, C. Guy Lane, 937.
Bilious Attacks in Children, Philip S. Potter, M.D., 55.
Bladder, the care and management of tabetic, J. Dellinger Barney. I. Diagnosis, 933. II. Etiology, 985.
Book Reviews. James M. Anders, a textbook of the practice of medicine, 64; Harold Leslie Barnard, contributions to abdominal surgery, 263; W. Bateson, Mendel's principles of heredity, 138; Gustavus M. Belch, practical suggestions in borderland surgery, 701; August Bier, Bier's textbook of hyperemia, as applied in medicine and surgery, 701; E. Stanmore Bishop, lectures on surgical nursing, 701; J. Bland-Sutton, the diseases of women: a handbook for students and practitioners, 623; Alfred Bruck, the diseases of the nose, mouth, pharynx and larynx, 262; Joseph D. Bryant and Albert H. Buck, American practice of surgery, 409; Walter L. Burrage, gynecological diagnosis, 808; Aldo Castellani and Albert J. Chalmers, manual of tropical medicine, 370; Mrs. Burton Chance, the care of the child, 227; H. J. Jackson Clarke, congenital dislocation of the hip, 444; Arthur Cooper, the sexual disabilities of man and their treatment, 920; Frederic J. Cotton, dislocations and joint fractures, 483; L. R. G. Crandon, surgical after-treatment: a manual of the conduct of surgical convalescence, 369; C. W. Daniels, tropical medicine and hygiene, 550; Lavinia L. Dock, hygiene and morality, 334; William James Dugan, handbook of electro-therapeutics, 740; Paul Ehrlich and his collaborators, studies in immunity, 369; C. A. Ewald, the diseases of the thyroid gland: myxedema and cretinism, 827; Louis Fischer, diseases of infancy and childhood, 588; William Paul Gerhard, the water supply, sewerage and plumbing of modern city buildings, 137; Achille de Giovanni, clinical commentaries deduced from the morphology of the human body, 739; Hollis Godfrey, the health of the city, 295; M. Louise Greene, among school gardens, 64; Ernest W. Grove, a synopsis of surgery, 306; Winfield S. Hall, nutrition and dietetics, 102; the Harvey lectures, 1907–8, 138; the Harvey lectures, 1908–9, 740; Frederick P. Henry, founders' week memorial volume, 843; George Howard Hoxie, symptomatic and regional therapeutics, 662; Woods Hutchinson, the conquest of consumption, 444; Woods Hutchinson, preventable diseases, 444; Adolph E. Ibershoff, physiology and pathology of the semicircular canals, 844; the international medical annual, 64; Robert Jardine, clinical obstetrics, 296; R. Llewellyn Jones, arthritis deformans, 138; George M. Katsainos, prophylaxis and treatment of syphilis, 623; W. W. Keen, surgery, its principles and practise, vol. v, 408; Robert Coleman Kemp, diseases of the stomach and intestines, 370; E. Heinrich Kisch, the sexual life of woman in its physiological, pathological and hygienic aspects, 482; Ernest Blake Knox, aids to microscopic diagnosis (bacterial and parasitic diseases), 517; Henry Koplik, the diseases of infancy and childhood, 138; Ralph Winnington Leftwich, an index of symptoms: with diagnostic methods, 227; Graham Lusk, the elements of the science of nutrition, 102; G. Betton Massey, ionic surgery in the treatment of cancer, 776; Isabel McIsaac, the elements of hygiene for schools, 138; W. C. Bosanquet and H. S. Clogg, the medico-chirurgical series no. 2: the stomach, intestines and pancreas, 263; the Medical Record visiting list, or physicians' diary for 1911, 881; Robert Milne, a plea for the home treatment and prevention of scarlet fever, 808; Robert T. Morris, dawn of the fourth era in surgery, and other short articles, 841; B. G. A. Moynihan, the pathology of the living and other essays, 296; P. Lockhart Mummery, diseases of the colon and their surgical treatment, 843; new and non-official remedies, 1910, 64; Albert J. Ochsner and Ralph L. Thompson, the surgery and pathology of the thyroid and parathyroid glands, 334; J. Bergen Ogden, clinical examination of the urine and urinary diagnosis, 334; G. E. Partridge, an outline of individual study, 307; Friedrich Pels-Leusden, chirurgische operationslehre für studierende und aerzte, 740; the practitioner's case book, 701; Walter L. Pyle, a manual of personal hygiene, 263; Ernst Romberg, a textbook of the diseases of the heart and of the blood vessels, 368; Thomas Morgan Rotch, living anatomy and pathology, 296; O. Rumpel, cystoscopy as adjuvant in surgery, 920; G. E. de Schweinitz, diseases of the eye, 517; Septimus Sisson, a textbook of veterinary anatomy, 880; Charles B. Slade, physical examination and diagnostic anatomy, 740; Myer Solis-Cohen, the family health, 36; Morse Stewart, pocket therapeutics and dose book, 64; Lewis A. Stimson, a practical treatise on fractures and dislocations, 296; Emily A. M. Stoney, practical points in nursing, 843; John M. Swan, prescription writing and formulary, 102; Frederick J. Taussig, prevention and treatment of abortion, 297; E. Q. Thornton, dose-book and manual of prescription writing, 36; Frederick Treves and Jonathan Hutchinson, a manual of operative surgery, 482; H. E. Wingfield, an introduction to the study of hypnotism, experimental and therapeutic, 881; Francis Carter Wood, chemical and microscopical diagnosis, 740; A. E. Wright, studies on immunization and their application to diagnoses and treatment of bacterial infections, 297; Macleod Yearsley, a textbook of diseases of the ear, 137; Eugene S. Yonge, hay fever and paroxysmal sneezing (vasomotor rhinitis), 881; Philip Zenner, education in sexual physiology and hygiene: a physician's message, 881; George Dock and Charles C. Rass, hookworm disease, 958; Anthony Bassler, diseases of the stomach and upper alimentary tract, 998; Edmund Cautley, the diseases of infants and children, 998.
Brain and Other Visceral Weights in sixty-six subjects showing carcinoma, Newell B. Burns, M.D., 222.
Brown-Séquard's Epilepsy in the Guinea Pig, report of a study of, A. E. Taft, M.D., 868.

Cæsarean Section, extraperitoneal, James Lincoln Huntington, M.D., 911; an historical notice of the operation of, from the first operation to the middle of the eighteenth century, Charles Greene Cumston, M.D., 316.
Cancer of the scrotum, Robert M. Green, M.D., 755, 792.
Carcinoma, note concerning brain and other visceral weights in sixty-six subjects showing, Newell B. Burns, M.D., 222.
Children, the hygienic and dietetic treatment of delicate, by the class method (abstract), Wm. R. P. Emerson, M.D., 326; bilious attacks in, Philip S. Potter, M.D., 55; tuberculosis problem in, John B. Hawes, 2d, M.D., 904.
Cholelithiasis, Richard F. Chase, M.D., 639.
Common Colds, the etiology of, A. Coolidge, Jr., M.D., 58.
Congenital ophthalmoplegia externa, S. G. Webber, M.D., 721.

Vascular System, some observations on the surgery of, Joshua C. Hubbard, M.D., 391.
Vitalism in Medicine, the doctrine of, M. G. Seelig, M.D., 825.

Wound Infection, analysis of, in one thousand consecutive clean operative cases, W. P. Graves, M.D., 610.

Shattuck Lecture.

A CRUSADE AGAINST SYPHILIS AND GONORRHEA.*

BY FREDERIC HENRY GERRISH, M.D., LL.D., PORTLAND, ME.

A few years ago, in conversation with a distinguished Fellow of this Society, whose knowledge of syphilis is profound, I asked his opinion as to the prevalence of that disease in this community. A look of great seriousness came into his face, and, after a significant pause, he said, "Of course, you know that nobody can answer that question with precision; but sometimes I would not avouch for anybody's freedom from syphilis outside of my immediate family." This statement was not intended to imply that probably only one household was uncontaminated by the malady in question, for my friend is not such a cynic as Ricord, of whom Dr. Holmes said that he was "a skeptic as to the morality of the race in general, who would have submitted Diana to treatment with his mineral specifics, and ordered a course of blue-pills for the vestal virgins"; but was merely meant to convey the idea that, in moments of depression, induced by frequent discoveries of syphilis in cases where its existence could not fail to cause a shock of alarm and disgust, he felt himself secure against surprise at its revelation anywhere.

Doubtless every one present has seen in recent literature estimates of the prevalence of gonorrhea, some writers alleging that 80 or 90% of the adult male population either now has, or at some time has had, it. Without expressing confidence in the correctness of these figures, the most reluctant conservative must admit its wide distribution.

In the prescription of conditions under which the foundation establishing this lectureship is to be administered, one class of subjects particularly specified for treatment is diseases of the inhabitants of this commonwealth; and I have begun my essay as I have in order to show that the requirement of the benevolent founder is complied with, and that, by so much, the subject to which I have the honor to ask your attention to-night is justified.

In the discussion of any subject it is important to avoid exaggeration, and the necessity for this caution is proportionate to the gravity of the topic under consideration. Extravagance weakens rather than strengthens the effect of a statement, and, consequently, in the propositions presently to be submitted, it will be my endeavor to keep so clearly within the bounds of admitted truth that nobody who is acquainted with the matters presented will have an opportunity for dissent.

As these statements are to a large extent elementary, it may appear unnecessary, and even impertinent, to introduce them before this learned audience; but there have appeared so many articles, seemingly authoritative, in which the innocuousness of syphilis is asserted, and objection made to certain things on which there should be unanimity of opinion, that I deem it important to present them.

* Read before The Massachusetts Medical Society, June 7, 1910.

FACTS ABOUT SYPHILIS.

About syphilis, authorities are agreed upon the following points:

It is constitutional, affecting every organ and every tissue.

It is either acquired or inherited.

The first evidence of acquired syphilis (the initial lesion) is the chancre.

The secondary manifestations of the acquired form, as well as the chancre, are powerfully infectious.

The tertiary lesions, while not clinically infectious, have no tendency toward spontaneous cure, but always toward destruction of tissue.

The cause of syphilis is either a microscopic parasite, *spirocheta pallida*, or some microorganism in whose life-cycle spirocheta pallida is a phase.

The acquired form is usually conveyed in sexual congress, and hence the disease is commonly called venereal; but in many cases it is communicated by immediate contact other than sexual, or through the intermediation of clothing, utensils and other objects of common use among the individuals concerned. Probably 5% of cases are thus caused.

The poisonous discharges of syphilis cease to be infectious in twenty-four hours, and in a fourth of this time, if dried; otherwise, the disease would be vastly more prevalent.

If the acquired disease is treated early and properly, it is curable to this extent: First, that the patient can beget (or conceive) offspring who are not syphilitic; and, second, that in about three fourths of the cases the patient will have no tertiary manifestations; but it is impossible to predict with certainty the event in any given case — no guaranty of future immunity can honestly be given.

Specific treatment needs to be continued vigorously at least two years, and one cannot be confident of the patient's ability to procreate non-syphilitic children until two years have elapsed from cessation of treatment and after the last appearance of a syphilitic symptom. In properly treated cases the time from infection to the period of safe propagation of the species is five years.

Doubt of diagnosis can be dissipated by repeated, thoroughly skillful examinations for the spirocheta.

Syphilis is one of the commonest diseases. While its prevalence cannot be precisely determined, those best able to judge declare their belief that 10% of the community are affected by it.

Scheube, in 1902, after investigation on a large scale, declared that syphilis has become almost universally prevalent in tropical and subtropical countries. When introduced into a community previously free from it, the havoc which it creates is appalling. This is illustrated in the Sandwich Islands, to which syphilis was carried by the sailors of Captain Cook. The present native

population is but a fraction of what it was before the Caucasian invasion, and the enormous reduction is evidently due to the ravages of this disease. To this unfortunate people civilization spells syphilization.

Of the acquired form, 80% of cases begin between the ages of nineteen and thirty-five.

Aside from the mortality of syphilis, its effect upon the health of the community is profound. It is a large factor in the causation of various diseases which are not generally associated with it in the public mind, and, in addition to these frankly expressed manifestations, it is at the bottom of much lowered vitality, which renders the system less resistant to the attacks of any disease.

It is not often named in mortality statistics, but it is responsible for a vast number of fatal results reported under other names, and probably is surpassed in deadliness only by tuberculosis. The death-rate of syphilitics is nearly 50% above that of non-syphilitics at corresponding ages.

It effects its destructive work by causing degenerative changes in various tissues, particularly those of the arteries and of the central nervous system.

One attack of syphilis usually insures immunity for life. "In the present state of our art a second attack of syphilis is the only possible proof that the patient has recovered from his first attack." [1]

Hereditary syphilis differs in character in no wise from the acquired disease, but there is no chancre.

It is extremely fatal, destroying many children *in utero*, many others soon after birth and others still after years of apparent health.

FACTS ABOUT GONORRHEA.

Gonorrhea is commonly a local disease, but its poison occasionally enters the system and causes trouble at points far from its usual sites.

Practically it is almost exclusively venereal in origin, and it is acquired only through contagion.

In the male it attacks primarily the urethra, from which it may extend to the bladder, ureters and kidneys, and to the true genital passages, the seminal vesicles and the testicles.

In the female the same urinary track may be followed; but more frequently the genital passages are involved in the extension — the vagina, the cervix, the uterine body, the oviducts, from which the disease may travel to the pelvic peritoneum.

Mortuary lists rarely if ever include its name, but indirectly it probably causes more deaths than does acquired syphilis, being responsible for most of the suppurative salpingitis and a very large proportion of the cases of fatal peritonitis in women.

Short of destroying life, it greatly reduces capacity for work and causes an enormous amount of hopeless invalidism, especially in women.

In relation to the married state its consequences are momentous, in this respect rivaling syphilis. It is believed to be accountable for more than 40% of the barrenness in childless marriages. No other disease is as potent in the production of sterility. In the male this comes about through the obstruction of the genital canal, causing scarcity, death and entire absence of the seminal elements (oligospermia, azoöspermia, necrospermia), and interfering with, if not entirely preventing, fertile coition; in the female by clogging the genital passage at some point, preventing the lodgment of the ovum and establishing disease which makes impregnation impossible.

The infective material of gonorrhea attacks the conjunctiva with especial virulence. Of all the total blindness in this country, 15% is traceable directly to this disease. From one half to two thirds of the cases of ophthalmia neonatorum are of gonorrheal origin.

The prevalence of gonorrhea is enormous. No other disease of serious character is as frequent in the period of life between eighteen and forty years. Doctors who specialize on venereal are apt to say that 90% of adult males have had it; but, without taking as cynical a view as this, we must grant that it is shockingly common, particularly among men, and the highest social ranks present as great a proportion of cases as do the lowest.

Formerly it was considered a trivial malady; then came a period in which its gravity was exaggerated; and now we are able to take a judicial view of it, considering it neither of trifling account nor hopelessly intractable, but a disease of great seriousness in its bearings upon the individual and upon the community, hygienically, sociologically and economically.

Though it is commonly treated insufficiently and improperly, the bulk of the cases are ultimately cured in the sense that they cease to be contagious; but an appreciable residue continue to be a source of infection for a long time. The gonococci may retain their vitality for years.

Among married women, about a third of the cases of gonorrhea owe their origin to the husbands of the victims, many of the latter being unaware of the nature and source of their malady. To women it is a worse scourge than any other form of venereal.

In chronic cases a special and expert examination, repeatedly made, is necessary to determine the absence of the gonococcus.

To one who is not familiar with the results of the modern study of these two diseases, some of these statements will seem extreme and unwarrantable, but their moderation will be acknowledged by those who have looked carefully into the subject. Even if these conclusions as to the prevalence and influence of syphilis and gonorrhea were to be cut evenly in two, the moiety would present a picture of horrible ghastliness. One who wishes to make a deep impression in this matter does not need to exaggerate; he may safely discard half of his facts and still have so much left as to run considerable risk of being thought sensational.

To what is to be ascribed this grave condition, this wide distribution of two diseases demanding

[1] E. L. Keyes, Jr. (1908).

such a toll of health and life? The answer commonly given is Prostitution. While admitting a large measure of truth in this reply, it may well be insisted that other factors enter into the case, without the recognition of which no consideration of the subject approaches adequacy.

USUAL TREATMENT OF PROSTITUTION.

Prostitution is one of the chief banes of civilization. Every code of laws recognizes its existence and makes a show of dealing with it. The methods adopted are multitudinous in their details, but all practically resolve themselves into two systems, — suppression and regulation.

Suppression aims at forcible extinction. The brothels are emptied, their proprietors are fined and imprisoned, their inmates are punished in various ways. The authorities nowhere persist steadily in their efforts, contenting themselves with spasmodic displays of virtue, which are usually productive of more harm than good. The expulsion of the abandoned women from the brothels drives them to practise solicitation on the streets, which had previously been free from the appearance of vice; or sends them into hiding in all parts of the community, often into domestic service in decent families, where their influence is most corrupting. Even if the officers of the law could close every house of ill fame permanently, and could compel every quondam inmate to abandon her pernicious trade, the method would always fail from its inability to reach the vastly greater number of clandestines, who are less openly avowed prostitutes, but nearly, if not quite, as injurious elements of the population. Prostitution will never be stamped out as long as there is a demand for the service which it supplies.

Regulation is really a system of licensing, but the latter name is vehemently objected to by some advocates of the method, and others, still more squeamish, insist upon the euphemism of "toleration," on the ground that prostitution is not approved or legalized, but only permitted. The distinction is too subtle to be perceptible to the ordinary mind, particularly as, whatever designation is employed, the intent is the same, namely, to make intercourse with prostitutes safe; and the rules are identical, to wit, registration, examination, certification and medication.

The avowed purpose of regulation is to afford to any married man who wishes to commit adultery, and to any bachelor who desires to perpetrate fornication, opportunity to gratify his sensual longings without danger of contracting disease. The same statute-book which declares adultery and fornication to be crimes and prescribes penalties for their commission, offers, through regulation, peculiar inducements for their commission. It is as if the law against stealing were to be mated with one which put a premium upon theft, or as if the statute forbidding criminal abortion were followed immediately by one providing ready means for relieving women of the products of unwelcome conception.

But the practical provisions of regulation are always so faulty as to excite amazement that anybody with cerebral development above that of amphioxus should be beguiled into approval of them, or should think that they afford reasonable assurance of protection against venereal disease. Two counts of the indictment against regulation are sufficient for its condemnation: First, the infrequency of the examination of the women, and, second, the entire omission of examination of the men.

First, as regards the women. Suppose that a prostitute is examined and receives a certificate of health, and, also, that a chancre appears within a few hours upon some accessible part of her genital tract. The number of men whom she can infect before her next examination depends largely upon her opportunities. Acton reports the case of one woman who admitted that she sometimes received forty men in twenty-four hours. Doubtless this is exceptional, though quite credible; a harlot, who knows how to make her favors peculiarly acceptable, always has an abundance of followers. The most conservative will grant that a woman with an unrecognized chancre, who is in moderately active practise of her vocation, will probably infect one man a day for a week, at the end of which time the regular hebdomadal examination will reveal her condition, and her career as a scatterer of pestilence will be arrested for a time. Every one of the men whom she has infected felt a large degree of security after inspecting her card, but experienced what we often hear called the stinging rebuke of misplaced confidence.

Second, as regards the men. A woman passes her medical examination and is legally qualified for a week of debauchery. Immediately comes a patron who has had gonorrhea but, not having felt any symptoms or noticed any discharge for a long time, considers himself cured. Still, however, there linger in the crypts of his urethral mucosa some gonococci, and the violent congestion of the genitalia, combined with the exertion and friction of the coition, arouses these microbes from their quiescence, excites their reproductive activity and results in their expulsion from their lairs and their introduction into the torrent of semen. Immediately active gonorrhea is started in the woman, and before her next inspection she has communicated the disease to a number of her paramours.

But these illustrations, though legitimate and not uncommon, are subtle compared with the more usual methods by which the venereal diseases are disseminated under the license system. Men who know that they have one or more of these maladies in an active form — an initial lesion, a secondary eruption, a persistent gleet — do not hesitate to seek their pleasure with prostitutes. They despise the whole class, however necessary they consider their services; they are absolutely regardless of the rights of the women as fellow human beings; they are brutally indifferent to the evil results of their own conduct to anybody whomsoever. The women, however suspicious of the condition of their patrons, do not dare to protest or to demand an inspection of the

latter with reference to their possible diseases, well knowing that they will be promptly mauled into submission on the slightest display of such insubordination.

It is perfectly manifest that all efforts to keep the women free from disease are fruitless unless corresponding rules are applied to the men who use them.

Some years ago a titled English woman [2] drew down on herself tremendous animadversions because, finding that Parliament was loth to abolish the "contagious diseases act," and wishing to show the absurdity and injustice of the law, and to create sentiment against the legalization of vice, advocated a statute compelling equal examination of men and women; and yet her position was strictly logical and scientific.

If any one who is acquainted with the facts is still unconvinced of the futility of attempts at regulation, further counts in the indictment may be brought forward, conspicuous among them being the incompleteness of the examinations of the women. Every student of the subject knows that an ocular inspection, however carefully made, cannot satisfy the demands of modern medicine. There may be no discharge of sufficient amount to attract attention and yet the mucosa of the cervix may swarm with gonococci, which, in the intense congestion attending copulation, awake from their torpor, and the disease, of which they are the characteristic elements, receives a new lease of life with all its old virulence and capacity for evil. But in no license system of which I have ever heard is microscopic examination demanded, although it is impossible to obtain the data necessary for an opinion without it.

One more factor demands mention in rehearsing the failure of regulation — the impossibility of including nearly all of the prostitutes. In the cities where the method has had its most complete trial the authorities have been obliged to confess that they have succeeded in registering only a fraction of them. As a rule the women detest regulation with its abridgment of their freedom, its insistence upon examination, its quarantine when disease is discovered, the infamy which it implies, the obstacle which it imposes to their return to decency of life and its almost certain destruction of the chance of marriage, which with most women is vaguely or confessedly a cherished hope; and they evade inscription as far as they are able. Its alleged protection affords them no advantages commensurate with its drawbacks. Only the most abandoned of the fallen women are willing to admit that prostitution is their vocation; it seems less of a slavery if they can delude themselves with the thought that it is an avocation. Obviously the difficulties of complete enrollment are insurmountable, and practically the system has nowhere approached thoroughness. The clandestine prostitutes far outnumber the registered always and everywhere.

This opposition on the part of the women has a counterpart in the attitude of the majority of the patrons of prostitution. The average man is allured by the secrecy which he has with a clandestine harlot; there is less of the confessedly commercial element in the transaction; it partakes more of the charm of seduction. He loves to deceive himself with the thought that the woman is not absolutely common; that not every comer can obtain the favors which are granted him; that he possesses a charm that compels a yielding of the feminine nature. Of course everybody else knows that this view is vain in every sense of the word. That which here is most pertinent to this discussion is that the spread of venereal disease is, proportionately to their number, the same among the registered and the clandestines.

All of this leads to the inevitable conclusion that it is impossible to guarantee safety from venereal to the patron of harlotry. As saith the scripture, "A whore is a deep ditch and a narrow pit."

In spite of all these facts, it is common to hear regulation advocated as a remedy for the evils of prostitution by the uninformed, not only among non-medical men, but even within our profession. Without making any careful study of the numerous trials of the method, captivated by the thought of easy control by legal enactment, they give this often exploited and thoroughly discredited system their enthusiastic support, and, with facile confidence in the soundness of their views, apply epithets of contemptuous characterization to those who, knowing the teachings of much history in this matter, venture to expose the fallacy of schemes of regulation.

ETIOLOGY OF PROSTITUTION.

If these much-vaunted and long-tried methods are useless, and worse than useless, are our resources at an end? Can nothing be done to abolish prostitution, or at least to diminish its deplorable effects? Are we to fold our hands in helplessness and try to ignore this curse? That surely is not the attitude of the profession in other matters which concern it. Prostitution, often called the Social Evil, may well be regarded as a disease of the body social, an endemic of almost universal prevalence. Approaching it as is our established custom in dealing with disease, having made a diagnosis, we seek for the cause, and, having found it, we remove it, if possible.

The elements in the etiology of prostitution are somewhat numerous, but for the most part not difficult of detection. Foremost stands the natural desire of the male human being for sexual intercourse. If one is justified in ascribing motives to nature, it may fairly be said that, in her anxiety to provide for the preservation of the race, she has oversexed mankind. From puberty onward the sexual appetite is so strongly evident in man that individual and public restraints are necessary to keep its manifestations within due bounds. Its mere existence is not deemed a sufficient warrant for its unlimited gratification, and society has prescribed conditions for its legitimate exercise.

[2] Lady Henry Somerset.

This element does not obtain to a very large extent in the case of females. There are but few Messalinas, hopeless sexual perverts; the vast majority of women have no very pronounced physical sexual feelings; and a minority are altogether deficient in this respect. But, while woman does not have to fight as much as man against appetite, other things are operative in leading her into the paths of vice. Poverty, ignorance of a useful occupation, inability to get an honest living, insufficiency of wages to afford decent support, the herding of large families in small tenements so that the sexes are brought into physical intimacy as abominable as it is inevitable, evil training and immoral associates, overweening love of dress and display, the attractions of a life of indolence, seduction effected through representations of its harmlessness or through promise of marriage, — these are prominent factors in supplying recruits to the ranks of prostitution. But more potent than any and all of these is ignorance of the laws of being, and of the ethical principles which ought to guide conduct.

Until all the vicious tendencies inherent in human nature are eradicated, we cannot expect to see prostitution entirely abolished; and hence it is practically certain that the diseases which it is so largely instrumental in disseminating will continue to exist to some extent; but the dispelling of the ignorance by which prostitution is mainly fostered will result in such a diminution of the lamentable practise that cases of these maladies will become relatively infrequent, obviously to the social and economic benefit of the race.

THE RATIONAL TREATMENT OF PROSTITUTION.

Education, then, is the principal remedy for the disease, since ignorance is the principal cause; and this education should be primarily physiologic, especially as regards the function of reproduction. When should it begin? Just as soon as the child shows interest in the subject! Probably this will be on the advent of a new member of the family. "Where did the baby come from?" The answer usually given is as silly as it is untruthful, and full of evil influence on the future of the innocent inquirer. All the wretched fables that do duty on such occasions will soon be detected by the child, and from that moment he will have no faith in the word of his deceivers. He sees that he has encountered a most attractive mystery, and he is bound to solve it. His curiosity is immensely excited by the attitude of his parents. Receiving no aid from those whose duty it is to help him, he goes elsewhere and gets something that passes for information, but is distorted by vicious purposes and stained with filthy slime of the gutter. A very serious phase of the matter is that the confidence which the child should have in his parents is destroyed by their contemptible lying.

Suppose that the parents recognize the question as not only unobjectionable, but highly commendable, inasmuch as it concerns functions, ignorance of which is responsible for incalculable mischief, and tell him the truth. What harm can result from his learning that the baby came from its mother's body, in which it had been growing a long time? There is nothing indecent or obscene in the fact; there can be nothing objectionable in its plain statement. And there is very great advantage in this frankness; the child, instead of being crushed by a deceitful rebuff, is honored by being taken into his parents' confidence; no mystery is made of the process which is a commonplace incident, and, consequently, there is little probability of his giving too much thought to it. He is told that it is not best to talk outside about such matters, for it is the affair of the family only; and this gives him a feeling of dignity and fellowship which draws him into nearer and dearer relation to those who should be his best and closest friends.

As puberty approaches, with its vague and disturbing feelings and thoughts, its physical and psychic changes, the father should tell his son, the mother her daughter, the meaning of the new functions which are developing; and thus events which otherwise are likely to produce profound perturbation are anticipated and explained and the crisis is passed without alarm or trouble.

SEXUAL CONTINENCE.

That is the fitting time for warnings about the temptations to which both boys and girls are exposed, for instruction concerning practises which are productive of lifelong shame, disease and disaster. Then, too, may well be corrected the popular error that sexual intercourse is a hygienic necessity.

That this opinion is sincerely entertained by many persons is illustrated by the case of the wealthy lady, of whom I have heard, who was making a solicitous search for a nice, healthy girl to serve as mistress for her son, who had just reached the age of puberty. Granted the premise that sexual intercourse is essential to health, the woman's position was strictly logical; it was her maternal duty to provide means for the exercise of her son's procreative function in such a manner as would prevent his contracting any contagious disease. The bearing of such an arrangement upon the life of the other young person concerned is too obvious to require extended comment at this juncture. The belief in copulation as a health measure probably had its origin in the desire to place the onus of immoral acts upon other than the real reason, which is lust. At all events, it is utterly mistaken. If a man has been accustomed for a long time to unrestricted indulgence of his sexual appetite, he has put himself into an abnormal condition not properly to be taken as a standard. His state is comparable with that of a person who has contracted the alcohol habit or any other drug addiction; deprivation is torture, and gratification, by giving a sense of comfort, conveys the impression of being requisite for well-being. To a man, however, who has not thus misdirected his sexual function, who pursues a normal physical course, and who keeps his mind free from lewd imaginings, complete abstention

is not only free from harm, but even beneficial. Perfect continence is a requisite in the training for severe athletic trials; and the internal secretion of the testes, which is so essential for the development of the adolescent into real manhood, can hardly be supposed to be valueless in subsequent years. All the great authorities are in agreement on this point, that abstention hurts no normal man. Finally, it may be set down as certain that, next to education, the best safeguard against sexual vice is association with chaste and refined women.

Later, when maturity is near, the young people should be advised concerning the marriage-state, and instructed to the following effect:

Marriage between persons whose physical or mental condition is markedly imperfect should be discouraged, for manifest reasons.

Marriage should not be regarded as a state in which prostitution is legalized. That it is so considered by men generally is undeniable. The physical element in love, whether avowed or denied, is prominent in the thought of the male, and he is usually insistent upon his so-called rights. Commonly his exactions are granted by the female, but without real comprehension of them, and with a toleration which comes from a sense of duty or of policy; but a relation which is characterized by brutal demands on the one side and helpless submission on the other is very far from ideal.

The rights of the prospective offspring and the responsibilities of their parents are entitled to most solemn contemplation.

THE SANCTITY OF LIFE.

In some ways we display a wonderful regard for life. For example, a man is found dead, evidently slain in cold blood. He is a notorious malefactor, guilty of a multitude of heinous offenses absolutely devoid of the qualities which make for good citizenship, an active pest to society. And yet, although everybody who knows about him is avowedly glad of this death and believes that the safety of the community is enhanced by it, all the necessary machinery of the law is immediately put in motion to bring his murderer to punishment. Detectives search every possible place of concealment; a reward is offered for his apprehension; when captured he is scrupulously guarded against possible injury from an excited populace; at his trial the state furnishes him with a learned advocate and pays the cost of his witnesses; on conviction he is given a long period for repentance and preparation for eternal residence in paradise; and, finally, he is deprived of earthly existence by a merciful and expensive process. Many thousands of dollars are lavished on the case and people eagerly read the details of the affair as a matter of vital importance. Outraged society has demonstrated that no member, however low, bad and objectionable, can be deprived of his life with impunity; that even if that life has been utterly misused, is entirely unfit for continuance, and even a menace to every other life in its neighborhood, it must not wantonly be cut short, and, if so destroyed, shall be avenged.

Such insistence on the sacredness of life is eminently proper; but does not consistency demand that this sanctity should be recognized in some other way than by safeguarding life and punishing those who recklessly disregard its rights? Should we not consider life so sacred that it should not be bestowed unworthily, that it should not be begun except in conditions favorable to its development into a blessing and not a curse to its possessor and to society? If the beginning of life was more regarded, there would be fewer cases of its vicious and violent ending. When the things which are already well known about the physiology of generation duly impress the public mind, then will the people cease to limit their consideration of the sanctity of human life to the circumstances attending its cessation; then will they perceive that an even greater responsibility waits upon the performance of the acts which determine the inauguration of life; then will they wonder that a function so prodigious in its bearings, so almost infinite in the extent of its influence, ever should have been regarded by persons esteemed thoughtful and humane as a triviality, a subject for ribald jesting, a thing obscene, indecent and shameful; then will they appreciate the truth that the beginnings of life are so sacred that no statement can exaggerate their holiness, no preparation of body and mind be too perfect for the function installing them.

The progeny should not be unintended, or begotten when the parents are in other than favorable condition. Every child has a right to an inheritance of good physical and mental health, and is unlikely to have it if he is conceived when his father and mother are feeble or depressed in mind or body; every pregnancy should be a cause of rejoicing to all concerned, and then the little one will have a warm welcome ready for him, and the prospect of a felicitous disposition.

THE BEST SIZE OF A FAMILY.

If the married are careful to observe the rules already given, they will probably have no need of advice as to the size of their family; the good sense which has guided them in the other things will dominate their conduct in this. But so much has been said of late on this subject that it may pertinently be touched upon here.

We have heard a great deal about so-called "race-suicide," the implication always being that citizens owe it to the state to have large families. The leading apostle of this doctrine speaks with the confidence of one having authority, and not as the scribes. But prodigious personal popularity and exuberant willingness to criticise and advise on every subject within the entire range of human knowledge and speculation are not invariably associated with encyclopedic information and judicial cast of mind; and, at the risk of violent denunciation, one may venture to suggest that another opinion is worthy of entertainment. Both science and philosophy

have arrived at the opposite conclusion. Quality is much more desirable than quantity; indeed, the latter may be expected to diminish the former. As a rule, the highest physical types occur in the smallest families. Prof. Franz Boaz, of Columbia University, has plainly shown that improvement of physical development attends reduction in the size of families. "In other words, nature seems to be subtly protesting against overbreeding by stunting the growth of superfluous children."

Herbert Spencer, the greatest of philosophers, says:[3] "Further evolution, causing along with higher nature diminished fertility, and, therefore, smaller burdens on parents, may be expected to bring a state in which, far more than now, the pleasures of adult life will consist in raising offspring to perfection, while simultaneously furthering the immediate happiness of offspring."

"Only as fast as fertility diminishes, which we have seen it must do along with further mental development, can there go on such diminution of the labors required for efficiently supporting self and family that they will not constitute a displeasurable tax on the energies."

In addition to the injury to parents and children when the latter are too numerous, the augmentation of a family beyond the capacity of the parents properly to support and train imposes an unwarrantable burden upon those in the community who are more honest and provident and sufficiently high-minded to deny themselves indulgences to which their sense of right and justice objects. The intentional limitation of offspring within the bounds of suitable maintenance is a duty alike to the progeny and the community.

Doubtless members of reigning families in monarchies are impressed with the obligation to pay the price of their royalty in part, at least, by keeping the strain in existence, and the same may be true of other titled personages; but I am not aware that I have encountered a man who could truthfully say that he had begotten his children in response to a prompting of duty to society. Many men desire offspring from love of children, from an ambition to perpetuate their name, from a wish for heirs to their estate; many without any definite wish for them, accept what come with patience and find that toleration develops into affectionate enjoyment; many, unfortunately it must be said, regret the advent of the newcomers, and treat them as if they were unjustified intruders, viciously thrusting themselves into an already overburdened family; and all of these parents — those who welcome their progeny with delight, those who have to become reconciled to what was originally an unhappy fate and those who always abominate their self-imposed burdens — on occasion accept the plaudits of certain pseudo-philosophers for their activity in performing their duty as good citizens, and not infrequently swagger a little in complacent contemplation of their superiority to their childless associates. It may well be doubted, however, if any one of them had in mind for an instant a duty to the state in contracting marriage or in performing any act in that relation subsequently. It is not altogether pleasing to think, as we must, that most of us are accidents; to recognize the unquestionable fact that men who are scrupulously careful about the breeding of their dogs, their horses, their swine, their barnyard fowl, are absolutely careless about the generation of their own kind. Reason guides in all the other cases, and passion in the one which is of infinitely more importance. That a citizen has a duty to the community in the matter of offspring is perfectly plain, but it does not lie merely or mostly in the direction of numbers. He may, as Spencer remarks, "fitly discharge his indebtedness in some other way than by adding to the population." President Hall, of Clark University, says in a recent article: "Many intelligent people, whose constitutions are tainted or handicapped by disease, deliberately refuse to produce children upon whom it can be entailed. This is a species of intellectual and moral heroism as splendid as anything exploited in ancient song and story."

However earnestly one wishes his own country to become great in population, it is futile for him to urge his fellow citizens to consider it a duty to the state to beget a numerous offspring. Some governments have tried the experiment of offering a prize for every child in a family above a stated number; but the effect is the rewarding of improvidence and putting a premium on the production of individuals who are more likely to be a burden than a help to the nation. It is entirely safe to say that no honest and sensible man is actuated by the hope of pecuniary gain in adding to his family; the prize does not compensate for the increase of the expense of rearing the brood. It is well known that the feeble-minded are generally very prolific; but their contributions to the population markedly diminish the strength of society. *Homarus americanus* has a hundred thousand offspring a year, but nobody wishes to be classed with the lobster.

But there are those who preach the doctrine of great families, not as a duty to the state, but on what they consider higher grounds. They declare that so-called "race-suicide defeats the purpose of creation, which is to reap a crop of souls for heaven."[4] Such teleological perception, such acquaintance with the intents of omniscience and omnipotence, so far transcend any knowledge of mine that I must confess my incompetence to discuss the matter from that point of view.

HOW SEX-EDUCATION SHOULD BE GIVEN.

The teachers of the children should be their parents, and we, the trusted physicians, should teach those parents. Not only this, but we owe it to the community to insist upon the importance, the essentiality, of this instruction. Our profession as a whole has too long neglected this great

[3] The Principles of Ethics.

[4] Quoted from an address by Father Isidore in Holy Name Cathedral in Chicago, March 10, 1910. Bishop Canevin, in a letter to priests of the Pittsburg diocese, February, 1910, recommends early marriage, says that the primary end of marriage is that children may be born and educated, and speaks of the right of children to be born

duty. Some, indeed, have recognized and have done it; and in saying the things that I do in this hall, dedicated to and bearing the name of one of your greatest and best-beloved physicians, a man of saintly character as well as exalted attainments, I feel that my words are spoken in singularly appropriate surroundings, that I breathe an atmosphere of sympathy and encouragement; and, if it is permitted to the spirits of the dead to revisit the scenes of their earthly endeavors, I believe that the purpose, at least, of this lecture is receiving the benediction of the pure-minded and philanthropic John Ware. "In 1847-48 many meetings were held in Boston to consider what means might be employed to lessen immorality and promote the well-being of the young. A committee was appointed to cause a book to be perpared which should deter from vice by a just exposition of its nature, its dangers and its effects," [5] and Dr. Ware was requested to write it. How well he succeeded may be judged from the estimate put upon it by the committee, who pronounced it "accurate, clear and truthful, but never offensive to modesty nor suggestive of evil thoughts." In the card-catalogue of the great library in this beautiful building are listed a number of articles by Dr. Ware, but it is safe to say that no one of them has attracted anything like the attention given to this little book, which passed through many editions and stands as a monument to his virtue and his aspirations for the race.

Doubtless many medical men since that time have lived up to these principles; and, to show that this line of thought is still followed, I will quote a few passages from a very recent paper by one of your most honored and distinguished physicians, Dr. James J. Putnam. In his very valuable article on "Personal Impressions of Sigmund Freud and his Work," [6] he says:

"Most of these criticisms have centered really, whether the fact was admitted or concealed, on the prominence given by Freud to the sexual element in the causation of the psychoneuroses. This was considered as a disagreeable topic, on which we had closed our eyes so long that we thought we might permit ourselves to regard it as legitimately outlawed. Its vast literature, well known to be of great importance, was repulsive and should not be seen upon our shelves. It counted for but little that this immense subject was daily and hourly thrusting itself upon our notice, whether as the cause of terrible sufferings, of terrible crimes, of terrible misunderstandings and misjudgments, and that it has played a huge part in the history of religion and of civic progress; those who have ventured to study it scientifically have been, nevertheless, regarded widely as disturbers of the peace."

"The principal objection to the discussion of sex questions, or the prejudice against it, rests on the assumption that 'sexual' means 'sensual.'"

"Conventional morals, important as they are, as indicating standards towards which every one should, for certain reasons, strive, are often, in a wider sense, extremely narrow."

It is extraordinary that such aversion to the mention of matters sexual should obtain in a land which is invariably reckoned as Christian, in which, indeed, the great bulk of the people are considered and wish to be considered Protestant Christians, belonging to that ecclesiastical division that bases its belief upon the authority of the Bible; for this holy volume, translated into more languages and distributed more widely than any other in the whole world, assiduously kept before the community by the churches, and pressed upon the attention of the people by great organizations, whose sole purpose is its universal dissemination, treats affairs of sex in the frankest and most matter-of-course way. The organs of generation, the function of reproduction, the most intimate physical relations of men and women, the permitted and forbidden circumstances of sexual conduct, are all mentioned with a freedom which is surpassed in no book, which is much esteemed, excepting that other great oriental work, the "Arabian Nights' Entertainments," — the most marvelous and fascinating collection of romantic literature on earth, — and not in this in the expurgated versions most commonly known. From beginning to end the Bible unreservedly touches sexual subjects; and so marked is this fact that such a study of it as one would reasonably expect by those to whom it is constantly recommended as the most valuable and important book ever written, containing the profoundest wisdom, the most uplifting sentiments, the infallible code of ethics and the surest guide to immortal bliss, would so inevitably accustom them to familiar mention of everything relating to the processes of reproduction that there would be no shrinking from plain and necessary treatment of the subject. But everybody knows that this is not the case. The explanation must be found in the dense ignorance of the people concerning this great book. If they read it in any but the most perfunctory manner; if they attempted seriously to justify to their own minds the supreme place in their reverence which they unhesitatingly accord it; if they manifested in it anything approaching the interest that they show for the best seller among the trashy novels of the day, the result would be that they would not be shocked by the discussion of the vastly important questions in which the relations of the sexes are involved, for some knowledge of the generative functions would be so widely diffused that the education of the people which I advocate would be well begun. But to all but a minute minority the Bible is little if anything but a fetich — revered, kept in a place of honor, held to be a necessary part of the furnishings of a house, a talisman, a protection against evil spirits, a ticket to a reserved seat in the sempiternal choir, a fire-insurance policy on the soul. Parents give their children the Bible with the injunction, expressed or implied, to read and study it. Can such persons reasonably object to having their children given frank, pure and intelligible information about the functions on which

[5] Quoted from the preface of "The True Relation of the Sexes."
[6] Jour. Abnorm. Psychol., February, March, 1910.

the perpetuation of the species depends, whose abuse and perversions are responsible for a large part of the miseries of the race? The objection could not consistently be made by any man, whether Catholic or Protestant, who believes that he is made in the image of the God which he worships, for he can find no warrant for the idea that the resemblance embraces all other parts and stops short at the reproductive; but, on the contrary, he cannot fail to remember that his belief includes the acceptance of a begotten son of God.

The clergy is far from blameless in this matter, in that they avoid dealing in any way with the subjects here discussed. How refreshing it would be to hear from prominent pulpits sermons on such texts as the following:

"There is fornication among you," I Cor. 5 : 1. It is the "will of God that ye should abstain from fornication," I Thess. 4: 3. "Nor shall a fornicator inherit the kingdom of God," I Cor. 6: 9. "The man that committeth adultery, even he that committeth adultery, shall surely be put to death," Lev. 20: 10. "Whoso committeth adultery lacketh understanding," Prov. 23: 27. "When any man hath a running issue out of his flesh, because of his issue he is unclean," Lev. 15: 2.

On the other hand, the public almost universally shows in an unmistakable way that it has a salacious taste whenever a scandal involving sexual performances becomes the subject of judicial investigation. Pious Christian parents, who think it outrageously indelicate that any one should suggest instructing their children along lines necessary for the latter's protection from immorality, disease and death, devour with feverish eagerness all the shocking details of the lewd performances of a low and worthless creature who has lifted himself out of utter insignificance by the magnitude of his crimes. Day by day for months they greedily seize upon the newspapers, which present in ghastly minuteness tales of filthy vice, which can have only a demoralizing influence upon the community; and these family-journals grace the homes of the righteous and become potent factors in the education of their children.

TREATMENT OF SEXUAL CRIMES.

Even if we could banish every particle of the ignorance of the laws of life which enters so largely into the etiology of prostitution, there would still remain other causes demanding attention. These, however, are not technically within the domain of the physician and are properly left to the care of the moralist, the philanthropist, the sociologist and the economist.

But while every available agency is employed to the uttermost in the effort to right the wrong, the trouble remains and cannot be ignored. Even when the physician knows the source of a malady and is working wisely for its suppression, it is necessary to do something for the temporary relief of the patient. The body social is suffering with the disease called prostitution. The removal of the conditions causing it can be effected but slowly, and meantime active treatment is called for.

There are at present many laws against sexual crimes, but an element of weakness in some of them is the disproportion between the penalty and the offense: in some cases a major infraction bringing a light sentence, while a comparatively trivial one is severely punished. It is merely another instance of the inconsistency and unreasonableness of the usual attitude to matters sexual. Take, for example, the case of the poetic genius, who brought obloquy upon himself and a sudden and disgraceful end to a brilliant career, by his perpetration of a crime so abominable as to excite universal disgust. If he had seduced an ignorant and trusting maiden, or laid himself liable under the bastardy act, or been corespondent in a suit for divorce, he might still have been admitted to the houses of the great and opulent, and have continued to be the pet of lovers of poetry, the drama and astounding eccentricity. Apparently the blasting of an innocent young life, the imposition upon the community of an illegitimate child and the invasion and destruction of a previously happy home are offenses easily to be condoned; but a sexual act which does none of these things, and affects only the two participants, is worthy of years of incarceration at hard and ignoble labor and heart-breaking ostracism for life. The man was clearly a sexual pervert, and his act, revolting and filthy as it must seem to any normal mind, recalling the vices of Sodom and Gomorrah, bears no comparison with those with which it is contrasted, either in its physical, moral or social effects.

There is a great lack of appreciation of the relativity of sexual crimes on our statute-books, and a careful revision on lines of sense and justice is much needed. But public sentiment should not be content to let this class of offenses go unrebuked, as they commonly are now; it should open its eyes to the fact that adultery cannot be committed by one person only, and that the two who are always concerned in it are equally deserving of the penalty. If the public and the officers of the law were to take this view of such cases, and the same vigilance were to be manifested in bringing them to justice as is exercised in the enforcement of some laws of less importance, prostitution would receive a staggering blow.

A peculiar phase of this subject has recently attracted the attention of our national government, and Congress has published the report of a commission of investigation,[7] from which I I quote a few sentences. "The importation of women for immoral purposes has brought into the country evils worse than those of prostitution. In many cases the professionals who come here have been practically driven from their lives of shame in Europe on account of their loathsome diseases; the conditions of vice obtaining there have even lowered the standard of degradation of prostitution formerly customary here." "Both from the investigations of the commission and

[7] Senate Document No. 196, Sixty-First Congress, Second Session

those of the Bureau of Immigration, it is clear that there is a beginning, at any rate, of a traffic in boys and men for immoral purposes."

But this importation of women is not the worst crime which has lately been disclosed. "The recent examination of more than two hundred 'white slaves' by the officers of the United States District Attorney at Chicago has brought to light the fact that literally thousands of innocent girls from the country districts are every year entrapped into a life of hopeless degradation and slavery because parents in the country do not understand conditions as they exist and how to protect their daughters from the 'white slave' traders, who have reduced the art of ruining young girls to a national and international system." "The radical remedy is in the home. Every mother should teach her daughter the mystery of life. Ignorance is a poor protector of innocence." [8]

Nobody can escape the conviction that it is the clear duty of every citizen to give all possible assistance to the officers of the law in their efforts to exterminate this awful abomination.

In advocating the instruction of children by their parents, and of parents by physicians, I have assumed that our profession is already qualified for this important service. To speak with perfect frankness, however, it must be admitted that this assumption is not entirely correct; the profession itself needs education in this direction. The avoidance of the scientific discussion of sex matters has become a fixed habit and cannot be readily overcome. But, stupendous as is this whole task of education, it should not appall. It must be undertaken, and neglect to do our part will count to our lasting discredit.

A CAMPAIGN OF EDUCATION.

The first campaign of the crusade, then, must be entirely educational. Already organizations have been formed for this specific purpose; but, in my judgment, they are not destined to accomplish as much as could be done through a different agency. The profession and the public are much more likely to be influenced in the desired direction if the instruction is offered by a great society, which is long established and widely known and honored, conducted by famous men, powerfully equipped in personnel, in traditions of the best methods, in a record of large achievements and in financial resources. A committee of such a society, composed of earnest, well-poised, altruistic men, who are interested in the work, would first assemble the forces of the several associations committed to this service, and unify and coordinate their various activities so that no effort would be lost by a duplication of work. Then a scheme would be adopted for reaching the public through the press. The newspaper syndicates afford the most accessible paths to the desired audience. A single one of these supplies material to 4,700 weekly journals, which reach, according to a conservative estimate, three million readers every fortnight. A short article would be furnished to each syndicate every week, and a paper by some distinguished author once a year to each of the great monthly magazines of general scope. Nothing, of course, would be published that was not strictly true, properly stated and entirely free from tinge of sensationalism, for every word would have the sanction of the central authority.

Some one may ask if the public would favor or even endure such a series of articles. The answer is found in the demonstration that has already been sufficiently made. For example, a certain high-toned journal, designed expressly for the reading of women, and with a circulation of a million a month, has had more than one temperate but plain-spoken article on these topics, and this is not a solitary example. The people are more than ready for whatever we have to tell them along these lines. Approval of this method is already given by the BOSTON MEDICAL AND SURGICAL JOURNAL, whose utterances we all admit are *ex cathedra*, in a recent editorial, commending an article on "Preventable Blindness" in *McClure's*, saying, "It is an example of the way in which the modern magazine may be made the vehicle for disseminating among the people the kind of information which they should and must have before they can reasonably be expected to co-operate in great measures of public progress, measures for which we cannot hope success without such co-operation."

The profession would be reached to some extent by these papers and magazines; but it should be more particularly approached through the medical journals by means of signed articles from the recognized authorities. There is needed an incessant, tireless presentation of the subject, so long continued that the densest intellect will be penetrated, the dullest mind awakened, the most obstinate objector convinced.

SYPHILIS AND GONORRHEA SHOULD BE REPORTED.

In a year or two legislation would be sought and obtained. At first, it would probably be politic to ask only for the compulsory reporting of cases of syphilis in its contagious stages, and of gonorrhea, thus putting them on the plane of other communicable diseases. The profession knows that this is the correct course to pursue, that logic, consistency, duty as guardians of the public health demand it. In New York City, in 1900, there were reported 41,145 cases of tuberculosis, scarlatina, measles, diphtheria, variola and varicella; and the venereal morbidity, estimated conservatively, was 225,000. If that is thought too high, quarter it, and the result gives 15,000 more than the six other diseases; divide it by 5 and there is still a large excess of venereal. Syphilis and gonorrhea should be reported for exactly the same reason that the other infectious diseases are reported — because society has a right to protection from them. The fact that they are contracted so largely in the commission of acts which are not only immoral, but forbidden by law, is not only not a reason for concealing them, but an added reason for exposing them.

[8] Edwin A. Sims, United States District Attorney of Chicago, quoted in the *Outlook*, March, 1910.

In what other case is it ever alleged, as an extenuating condition, that infraction of law is an essential element in the offense? Syphilis and gonorrhea are acquired either innocently or in the pursuit of vicious indulgence. If innocently, the reporting should bring no shame; if viciously, the victim is estopped from demanding that measure of sympathy to which the burden of grave disease ordinarily entitles him; and the community has a right — it is its duty — to protect itself against his communicating his horrible malady to others. You and I, and those whom we hold most dear, are more worthy of protection than is the sensualist, whose moral perception is so blunted that he insists that we should suffer and die rather than that he should endure any curtailment of his iniquitous pleasures, or should incur the odium which his criminal conduct merits.

These views are opposed on various grounds, and the arguments against them will be met and answered.

It is objected that a law should be the expression of the deliberate will of the majority, and that the proposed statute is not called for. To this it is answered that, if the law-makers did nothing except in response to popular demand, the General Court would have but little to do. There was no such clamor for the establishment of your State Board of Health, the first in the country. A few sagacious and philanthropic men — a minute minority of the population, and almost the only persons in it who had a grounding of sanitary knowledge — persuaded the legislature of the value of the proposed statute, which proved to be of inestimable worth, especially in educating the people. There are countless cases in which the populace has derided, vilified, abused and injured men of advanced views, who have proposed wise schemes, which long afterward were adopted to the great advantage of the community. It is hardly thinkable that, if people generally knew, as they should know, of the perils of syphilis and gonorrhea they would not insist upon the suggested addition to the law.

A second objection asserts that the law would be useless, because, it is said, physicians would not report their cases. Doubtless this would be largely the fact at first, as it was with tuberculosis, and still is to some extent; but gradually the wisdom and necessity of the practice would penetrate and pervade the understanding, and compliance would become habitual.

Next, it is asserted that a law unenforced has an evil influence on the public regard for all law. It is true that a law needs the approval of a good part of the community in order to be thoroughly effective; but it does not follow that it is useless or harmful if it is not generally approved. The lack of sympathy may be due to failure of appreciation; and, if the law is sound, approval will grow just as comprehension enlarges. But, more than this, there is a distinct value in legal recognition, for every law is largely educational; it reminds the people of matters previously unconsidered, and, because it is a law, it comes to them with a predilection in its favor. As was said by your eminent Fellow, Dr. Arthur T. Cabot, at last year's meeting of the National Association for the Study and Prevention of Tuberculosis, "There can be no doubt that legislation looking to hygienic living had much to do with the decrease in tuberculosis which preceded the modern understanding of the disease, and the crusade against it." "The laws [are] often evaded." "Their full usefulness will not be reached until the public recognizes their necessity and demands their enforcement." "This enforcement, then, waits upon the education of the community." What is said here about tuberculosis applies equally to syphilis and gonorrhea. The law should require the reporting by householders, who know about cases in their families, and by all persons undertaking to treat these diseases, thus reaching charlatans and prescribing apothecaries.

It is, of course, objected that the code of ethics forbids the revelation of facts obtained in the privacy of the consulting-room, to which it may fittingly be replied that a code which prescribes protection of the guilty at the cost of the health and life of the innocent conspicuously requires revision. Our profession as a whole has too long given its tacit sanction to deeds which excite in its individual members abhorrence. We have permitted base men to take advantage of the provisions of our code and of our exaggerated and perverted notions of honor to shield themselves from the deserved consequences of their shameful acts. The adulterer has counted confidently on the grave-like silence of the physician, to whom he brings his case of venereal, knowing that, however base the relation which he purposes to sustain toward his trusting spouse, however reckless concerning the welfare of his possible progeny, and however frank in his expression of brutality in both these regards, the doctor may be depended upon to shield him by giving no warning to the party who is in such peril of wreck and disgrace. There certainly should be some way by which we can avoid becoming involuntary accomplices in crime; it should be impossible for any breaker of statute or social law to make us protectors of evildoers, particularly when, by such guardianship, we fail so strikingly in the foremost and most valuable of our functions — the prevention of disease.

How inconsistent is our attitude! A man suspected of leprosy, although pronounced by the highest authority on dermatologic matters to be free from the disease, is branded as a social outcast, subjected to constant inconvenience, discomfort and pecuniary loss, and deprived of his liberty for a long period, and all this in spite of the apparently well-grounded opinion of some experts that the malady is not contagious. Such a case is fresh in your minds. But a man in the acute stage of gonorrhea or syphilis, or even both of them, is allowed to roam without restriction among the people, possibly leaving his vile trail on every article and every person with whom he comes in contact, spreading the contagion of the most formidable diseases broadcast, and no one of

us utters a word of protest, except such as we speak into his regardless ears; no one is justified by the code in putting the richly merited "*cave canem*" upon him for all to read.

But we are asked if we should not be as close-mouthed as priests, who never reveal the secrets of the confessional. The cases are essentially different. A sinner confesses his misdeeds to a priest in order to obtain absolution, without which he does not expect to gain admission to paradise. Confession is a sacrament, enjoined in order that a guilty one, by acknowledging his offense, expressing repentance and avowing intention to avoid the sin in the future, may be forgiven by the earthly representative of the Deity. The Church insists that the father confessor shall keep inviolable the disclosure that is made to him, because, without confident assurance to that effect, the sinner might avoid confession, and thus, receiving no official forgiveness, would be in great danger of eternal damnation. It becomes to him a question between a chance of punishment while in the flesh and a far worse experience after death. The law sympathizes with the intent of the Church, and tolerates the sacerdotal attitude of silence.

When one goes to a physician, he seeks physical help. The intelligent patient reveals everything that he knows about his case to assist in the formation of a diagnosis; and he is aware that, if he is found to have certain diseases, the doctor is compelled by law to report the existence and nature of his case to the authorities, so that there may be no unnecessary diffusion of the malady. Naturally one prefers to have no publicity given to the fact of his ailment; but when a man comprehends the purpose of the law, when he appreciates that unless he sacrifices something of convenience, comfort and material good, his family his neighbors, his town, may suffer great loss in sickness and death, he yields obedience to these sane regulations. Thus the patient knowing that the law requires syphilis and gonorrhea to be reported to the board of health, the medical man is guilty of no branch of confidence in disclosing the character of the disease.

When the community has been educated to a proper appreciation of syphilis and gonorrhea, further legislation should be had, especially forbidding the marriage of persons in whom these diseases remain uncured; the making it a crime to communicate either of them; and the authorizing of a civil action in cases where a party who has been infected brings suit for damages.

How utopian this whole scheme seems to many of you I fully appreciate, for I have been arguing along this line for a third of a century and know that these views are not congruous with prevailing ideas and sentiments; but I am so thoroughly convinced of their correctness and of their ultimate adoption that I am content to leave the matter without further argument. Nothing that I have said is intended, or can be fairly interpreted, for the belittlement of any movement already undertaken for the stamping out of any disease. Our profession is capable of fighting many foes at once; and without diminishing the interest in any one of its campaigns, it can, and sooner or later certainly will, enlist heartily in the proposed crusade against syphilis and gonorrhea.

Original Articles.

HEMORRHAGE FROM THE KIDNEY.*

BY PAUL M. PILCHER, A.M., M.D., BROOKLYN, N. Y.,

Consulting Surgeon to the Eastern Long Island Hospital; Associate Surgeon to St. John's Hospital; Attending Cystoscopist to the Jewish Hospital.

THE origin of bleeding from the kidney can only be determined with accuracy (1) by surgical operation, or (2) by use of the cystoscope or segregator. Of these methods, the cystoscope is the more accurate, although errors have been recorded by both methods.

By the aid of the cystoscope we determine that the bleeding is coming from one of the kidneys, and what remains to determine is the probable cause of the hemorrhage. In some cases the amount of blood present is so large at all times that it is practically impossible to make a satisfactory cystoscopic examination.

DIAGNOSIS.

Before the cystoscope came into use, there were certain rules laid down for determining the source of hematuria.

1. *The color of the urine.* — In general it may be said that the brighter the blood, the nearer the source of the hemorrhage is to the meatus.

2. *The time of appearance of the blood.* Blood oozing from the urethra between the periods of urination is of urethral origin. Fluid blood passed at the beginning of urination comes from the prostatic urethra. When the first urine passed is clear and the second portion is bloody, the source is either the bladder or the prostate. Blood evenly mixed with the urine throughout the entire specimen is of renal origin.

3. *Shape of the clot.* — If the clot is long and narrow, resembling earthworms, it is supposed to be characteristic of renal hemorrhage. This, however, is very misleading. Large irregular clots suggest bladder origin.

4. *Facts learned from irrigating the bladder.* — If repeated washings of the bladder do not clear up the blood, the bleeding is probably of bladder origin. If the fluid returns clear after one or two washings, the bleeding is probably from the kidney.

5. *Microscopical examination of the urine.* — The appearance of blood, or numerous hyaline and granular casts, suggest renal origin of the hematuria. The finding of the eggs of the bilharzia is suggestive of bladder origin. Numerous crystals lead one to suspect stone. Tubercle bacilli, when found, are pathognomonic.

Cystoscopy. — The difficulties of making a satisfactory examination in the presence of hemorrhage have already been mentioned. Prolonged

* An address read before the Brooklyn Pathological Society, March, 1910.

rest, allowing only a small amount of fluid, the exhibition of sedatives, and ergot, may diminish the bleeding. If the bleeding is of bladder origin, great care must be used in irrigating. It is most important that the bladder should never be completely emptied, and only small amounts of fluid be used, injecting and withdrawing it slowly. If possible, do not irrigate more than once, and then attempt to make the examination.

If the vesical neck or prostate is the source of the bleeding, examine the base of the bladder first and then the trigone. Bleeding ulcerations, tumors and foreign bodies can be quickly detected, but the most confusing problem is to decide between the bleeding from an inflamed or ulcerated area near a ureter opening and bleeding actually coming from the ureter. Blood will sometimes settle slowly, and almost invisibly over a ureter opening, only to become evident as the urine swirls from the ureter and mixes with it. The mere contraction of the sphincter ureterica may produce the bleeding.

When inflammation of the bladder is not present, the recognition of blood spurting and oozing from an ureter mouth is unmistakable. With each contraction of the ureter a swirl of bloody urine is ejected into the bladder and the source of the hemorrhage is established.

It happens frequently, however, that at the time of examination no blood can be detected in the urinary efflux, either due to the temporary arrest of the bleeding or to the small amount mixed with the urine. In such cases there are generally characteristic appearances in the ureter mouths which attract attention. In renal varix, and renal tumors, these may be very slight. There is usually a slight blush to the tissues, an increase in the number of vessels crossing the lips of the opening, or a few scattered vesicles, or the mucous membrane may be slightly stained with blood pigment. In renal tumor there may be a puffiness surrounding the opening. If the renal pelvis is dilated, the orifice may appear darkly congested. Stone in the kidney pelvis does not usually cause much change in the ureteral opening, but the spasmodic contractions of the sphincter are more frequent.

Tubercular disease of the kidney usually produces characteristic changes which do not need description here.

ETIOLOGY.

Renal hematuria may be caused by trauma, drugs, certain foodstuffs and pathological conditions the result of disease.

Trauma. — When the hemorrhage is due to trauma, the history and the appearance of blood in the urine seldom calls for further examination; however, when the ureter has been divided, or the ureter has become plugged by a clot, blood does not appear in the urine.

Drugs. — The exhibition of cantharides and turpentine are the most common cause in this list. Of the foodstuffs, rhubarb, gooseberries, unripe apples and asparagus may all give rise to hematuria.

Hematuria of disease. — As an expression of intense congestion of the kidney in malignant fevers, the occurrence of hematuria needs no explanation.

Aside from this, the renal hematuria may be divided into

(1) Hematuria, without other symptoms, and

(2) Hematuria accompanied by definite clinical symptoms.

The most common causes of symptomless hematuria are, in the order of their occurrence,

(1) Acute and chronic nephritis.

(2) Calculus, renal tuberculosis and congestion of the kidney.

(3) Renal varix, an angiomatous disease of the papillæ renales.

(4) Papilloma, or malignant diseases of the kidney.

ACUTE AND CHRONIC NEPHRITIS.

Case I. *Bilateral renal hematuria. Chronic nephritis.*

A woman, aged fifty-five years, was referred to the writer by Dr. Louria. Her only symptom was the appearance of blood in the urine, evenly mixed with it. No clots were passed. There were absolutely no other subjective symptoms. The urine contained albumin and a few casts. *Cystoscopic examination* showed bloody urine coming from both ureter openings. Under medical treatment, the hemorrhage gradually disappeared. It is to be noted that there was no sudden increase of the bleeding at any time, and no clots were present, showing the even distribution of the blood cells. The condition was not affected by exercise.

Case II. *Unilateral renal hemorrhage. Interstitial and parenchymatous nephritis. Arteriosclerosis of kidney.*

Patient aged thirty-nine, male, Russian. No previous history of rheumatism, tuberculosis or hemophilia. Married fifteen years; six children; all well. Had measles when a child. Well until seven months ago, when he began to have pain in the sole of his left foot. He could not use the foot and could not sleep well on account of the continuous pain. This pain extended up as high as the middle of the thigh. The leg became cold and numb. Then the right leg became affected in a similar manner. His arms and hands then became affected. Treatment in the hospital improved his condition so that he was able to resume his work. During the period that he was in the hospital there was some spitting of blood and nose-bleed. There was a history of specific urethritis eighteen years ago, and also a history of a small ulcer situated near the meatus which remained for two months. There was no eruption.

Feb. 9, 1909, he noticed that his urine was red and that he was passing urine every two hours. Next day there was sudden severe pain on the right side posteriorly in the region of the kidney extending anteriorly downward to the groin. He had chills and fever. His urine was red for a few days, then there was an increased amount of urine which was normal in color for two days, when blood again appeared. Patient urinated every two hours, but there was no other symptom. He has never had a similar experience.

Examination of the heart showed the apex beat to be normal. No adventitious sounds or murmurs. The aortic second sound accentuated.

Arteries. — Temporal artery tortuous and visible. Brachial artery thickened and visible. Radial artery markedly thickened and tortuous. Femoral artery thickened with visible pulsation.

Pulse. — Small, slow, regular, and with high tension.

Liver and spleen. — Not palpable. *Reflexes.* — Present and normal.

Feb. 14, 1909, he had a severe attack of pain in the right lumbar region, and the muscles protecting the kidney region were rigid. There was extreme tenderness, especially at a point one inch below the intercostovertebral angle.

Urine. — Feb. 13, 1909, bloody, neutral, with large amount of albumin in proportion to the amount of blood present.

Feb. 19, 1909, amber; acid; reaction; 1015; moderate amount of albumin and few red blood cells and a few hyaline casts.

Feb. 20, 1909, no casts were found.

Blood examination. — Leucocytes, 11,000; polynuclear, 79%. Feb. 15, 1909, red blood count, 5,540,000; leucocytes, 16,000; polynuclear, 79%; hemoglobin, 120%. The red blood cells are very high in hemoglobin. Feb. 20, 1909, leucocytes, 17,000; polynuclear, 84%.

Blood pressure. — Feb. 14, 1909, 132 mm. of mercury. Feb. 19, 1909, 150 mm. of mercury.

Wassermann reaction. — Doubtful.

Feb. 20, 1909, *first operation.* Four-inch incision two inches above the crest of ileum, and evacuation of a retroperitoneal hematoma, extending down into the pelvis from the kidney region. This was drained. The blood from this hematoma was sterile. *Second operation* March 8, 1909, by Dr. Delatour. On account of persistent hemorrhage from the right kidney, with no other symptom excepting a slight increase in the temperature and progressive hematuria. The right kidney was removed. Following this operation, he made a temporarily good recovery.

Urine examination. — March 10, 1909, clear, acid, 1022, heavy trace of albumin, few pus cells, no red blood cells. March 12, 1909, clear, acid, 1020, heavy trace of albumin, few pus cells, no red blood cells. Urine, April 11, 1909, cloudy, acid, 1016, trace of albumin, few red blood cells, hyaline and granular casts. These casts were present until the end.

There developed symptoms of sepsis in other parts of the body, and April 10, 1909, an ischio-rectal abscess was evacuated.

The patient died a few weeks later of general septicemia. Examination of the kidney which was removed showed an advanced stage of arteriosclerosis of the vessels and chronic interstitial and parenchymatous nephritis.

RENAL VARIX.

In a recent article on this subject [1] the writer reported two personal cases of renal varix. To these, two additional cases may now be added.

CASE III. Patient referred by Dr. Harold Jewett. A man aged fifty years. Malaria and scarlet fever as a child; no venereal history. Four years previous to examination, without known cause, his urine became dark red or chocolate-colored. This discoloration of the urine lasted a month or two and then suddenly disappeared, and the urine became clear again.

Status praesens. — The patient had been drinking heavily. In October, 1908, he noticed the return of his former condition. There was no symptom other than a large amount of blood in the urine. This was more marked in the morning on rising, and cleared up somewhat as the day progressed. There was some increased frequency of urination during the day. He was very nervous and had lost considerably in weight. Physical examination showed his heart to be normal, his liver enlarged, but otherwise negative.

[1] Ann. Surg., May, 1909.

Examination of the urine showed the specimen to be loaded with blood, the cells sinking rapidly to the bottom of the glass container and the supernatant fluid retaining its red color, showing the presence of free hemoglobin.

Iron and quinine were administered in various forms; in November, the fluid extract of ergot in one-half dram dose every four hours was exhibited. At this time the urine was still loaded with blood. Two days after he began taking the ergot the urine became perfectly clear and remained so for two days; then it was more bloody than before. This continued for a number of days, and then, without any medication, the urine became clear again and remained so for a few days and the blood reappeared. Dec. 10, 1908, it was clear and remained clear the 10th, 11th, and the 12th of December, then the blood reappeared and was present off and on until April, 1909.

Cystoscopic examination showed blood coming from the left ureter.

The writer presented the history of the case before the Brooklyn Surgical Society and made a clinical diagnosis of renal varix.

May 1, 1909, the patient consulted Dr. Hugh Young, of Baltimore. He also found hemorrhage coming from the left kidney. He injected the pelvis of this kidney with 3 drams of a 1 in 500 adrenalin chloride solution. After a day or two the hemorrhage stopped and it did not return for about ten days. He returned to Brooklyn in the same condition as before.

Jan. 11, 1910, *cystoscopic examination* showed the left ureter opening normal in appearance and secreting blood-tinged urine at regular intervals. There were a moderate number of leucocytes, a few renal cells, with a few epithelial and red blood cells being excreted from the renal pelvis. Bacteriologic examination of the urine from the left kidney was negative. The renal pelvis was washed out with adrenalin chloride solution in order to check the hemorrhage temporarily.

Operation by the writer. — At the end of a week the left kidney was exposed and was found to be surrounded by a mass of fat and many fibrous bands which bound down the kidney. These were separated with much difficulty. In order to bring the kidney up out of the wound it was necessary to resect the twelfth rib. The kidney was somewhat congested and enlarged. It was bisected along Broedel's line, and the pelvis and all of the calyces were opened. The papillæ at the upper pole of the kidney were congested, and one of the lower papillæ showed on its surface a roughened, granulated mucosa, making it appear somewhat whiter than the other papillæ. After the kidney had been thoroughly inspected, and the varicose and congested condition of the papillæ noted and demonstrated to a number of the surgeons who were present, the two halves of the kidneys were brought together and sutured with two layers of mattress sutures, using No. 2 plain catgut. The capsule of the kidney was sutured with a separate catgut suture, a drain was inserted into the lower and central portions of the wound and the rest of the wound closed. The patient made an uneventful recovery, the blood disappearing from the urine within seven days after the operation.

A letter received from the patient three months after the operation stated that there had been no recurrence of the trouble, although the patient had continued the daily consumption of a large quantity of whiskey. It is now nine months since the operation and there has not been a trace of blood in the urine since that time.

The histories of these cases are very much alike. The patient, usually in good health, suddenly notices the presence of blood in the urine. There

is nothing to account for its presence; there has been no undue exercise, no injury, no infection, no history of renal colic; no pus cells, epithelial elements, crystals, tubercle bacilli or other abnormal ingredient found in the urine, other than blood, which is at first small in amount, then either increasing or decreasing, and oftentimes absent altogether; in some cases the amount of blood is influenced by exercise, while in others this plays no part. In two cases of my own, the quantity of blood seemed to be greater in the morning and to lessen as the day advanced. It occurs with varying frequency in both men and women over twenty-five years of age. Some patients have had alcoholic habits, while others have been total abstainers; in fact, there is no type of person in whom the disease has been more frequently observed. The hemorrhage may last but a few days, only to disappear and recur again after periods of weeks or months, or even years; or, again, it may be continuous from the first, causing progressive anemia.

As a rule, the urine is loaded with blood and, at times, with free hemoglobin; the blood cells are evenly distributed throughout the urine, appearing in all parts of it as it is evacuated from the bladder; clots may be found in the bladder, to be expelled at intervals; as the specimen stands, the cells rapidly fall to the bottom of the glass container; and it has been observed in my own cases that the urine retains its reddish color after precipitation of the cells, probably due to free hemoglobin.

The urine shows no evidence of renal disease other than a reaction for albumin in proportion to the amount of accompanying blood serum, excepting where nephritis is present, a condition which of itself may give rise to hematuria, but which should not be classed with these cases.

Rarely the patients complain of pain or distress in the affected kidney or over the bladder, but it has been observed in some cases that all of the pain and discomfort have been referred to the opposite kidney. The disease is always unilateral, and no cases, so far as I can learn, have ever been reported where the disease affected both kidneys. It is true that symptomless hematuria is frequently bilateral, but those are the cases due to malaria, hemophilia, drug-poisoning, nephritis or other causes quite different from those included in the present report.

Case IV. Referred by Dr. Kennedy. A man of seventy years of age. Patient had had no urinary symptoms until December, 1907. At that time, after a long carriage ride, he suffered from over-distention of the bladder, and when he voided his urine a blood clot was passed and about two quarts of urine. There was no symptom of any inflammatory process, colic, etc., simply hematuria. The hemorrhage continued for some weeks, stopped spontaneously and recurred again at short intervals. During the spring and summer of 1908, the patient states that there was no blood in the urine. In September he had an attack of cystitis which subsided. In September the blood again appeared in the urine and has been present off and on ever since. No special form of exertion seems to influence the hematuria. There has been some increased frequency of urination more marked at night. He urinates every two hours. He has not lost flesh or vigor and feels otherwise well. There is an organic lesion of the cardiac valves, but no edema or other symptom of cardiac disease.

Cystoscopic examination. — May 5, 1909. About 8 oz. of residual urine. Blood appeared only at end of quantity removed from bladder. Urethral distance, about 9 inches. Some obstruction in prostatic urethra; medium clear after one irrigation. Bladder mucous membrane shows slight chronic changes due to enlargement of median lobe projecting into the bladder. Left ureter opening normal and excreting clear urine with rhythmical contractions. Right ureter opening congested and shows a few vesicles at lower margin. The urine excreted appears to be almost pure blood, considerable in amount.

The fact that the hematuria has been symptomless, absolutely without pain, with no loss of flesh or strength, and no cachexia, has existed for eighteen months, and is confined to the right kidney, would suggest renal varix. Papilloma cannot be excluded. There have been no symptoms of stone. An examination of the urine for tubercle bacilli was negative. Hypernephroma would probably show a distinct afternoon rise of temperature and diminished amount of urine. Malignant disease would probably have caused some loss of strength. Upon examination of this case it was supposed that the hemorrhage might be due to his hypertrophied prostate, and an operation for the removal of the gland was under advisement. This was not done, however, and the patient refused operation on his kidney. His subsequent history has not been reported.

MALIGNANT GROWTH OF THE KIDNEY.

In renal tumor, the hemorrhage occurs suddenly. It seems little influenced by exercise. There may be a single attack during sleep, and then it will not occur again for weeks or months. This is especially true of carcinoma. At one time almost pure blood will be passed and the next urination will be perfectly clear.

Case V. Referred by Dr. Flannery. Patient a woman aged sixty-eight. Nine years ago we removed a large fibroid uterus. The patient has been well until the last six or eight months. Since then she has been somewhat weak, but otherwise her condition has been normal.

Jan. 1, 1910, she suffered from a sudden hematuria, which came on without symptoms, excepting an increased frequency of urination. This lasted but a short time and the urine remained clear for a week. At the end of that time there was another sudden appearance of hematuria without symptoms. Examination revealed an irregular, hard tumor occupying the position of an enlarged and slightly prolapsed kidney. Cystoscopic examination showed the bladder to be normal. Functional test of the two kidneys, passing the catheter into each pelvis, was made, using phenosulphonethalien. No urine was obtained from the right side, due, I believe, to reflex anuria. The urine from the left kidney flowed very slowly and the characteristic reaction of the test did not take place until thirteen minutes after injection of the drug. In a normal functionating kidney this should take place in from seven to nine minutes. It demonstrated, therefore, that not only was the right kidney diseased, but the left kidney also was not functionating normally. During the next twenty-four hours only 17 oz. of urine was passed, which bore out the above conclusion. The patient was examined again after two days, using indigo carmine, and only a faint

greenish color appeared in the urine from the left kidney after twenty-four hours. Operation was advised against. The patient died three weeks later in coma.

Calculus renal hematuria is usually small in amount and is increased by exercise. It rarely occurs without pain. Tubercular ulceration of the pelvis of the kidney gives rise to hemorrhage only through the rupture of a blood vessel, and its occurrence is not frequent, hemorrhage in tubercular disease being almost always accompanied by definite symptoms.

RENAL HEMATURIA ACCOMPANIED BY PAIN.

Renal varix, nephritis and tumors of the kidney seldom give rise to pain excepting that in the latter class, when the tumor causes obstruction or pressure from its size, pain may occur, but is easily diagnosticated.

Renal calculus is a most common cause of hematuria accompanied by pain in the region of the kidneys. Next in frequency comes tubercular disease and congestion or hyperemia due to numerous conditions and aneurism of the kidney. I will not here repeat what has already been said concerning the diagnosis of renal stone, excepting to emphasize the fact that usually the hemorrhage is small in amount. An exception to this is the following case:

CASE VI. Referred by Dr. Beasley. A printer, fifty-three years of age. Nine years ago was operated on by us at the Seney Hospital. In July, 1900, a hydronephrotic left kidney, with stone, was removed. At that time he suffered from intermittent attacks of pain in the left side and back, lasting ten or twelve hours; at such times there would be a change in the character of the urine, but no blood. At long intervals had some pain in the right side, but otherwise has felt fine and strong.

Status praesens. — Accustomed to pass considerable urine; would get up three or four times at night. Five weeks ago noticed some blood in the urine which had been passed during the night; then began to have trouble; pain started on right side under the lower rib and around toward the back; was continuous for short periods, very severe, felt as though he would like to double up. Growing worse, attacks became more frequent; hands and feet began to swell. Blood was continuously present in the urine after its first appearance. Patient thought the amount of urine passed was less during attacks of pain. Amount of blood in urine increasing. Was losing strength rapidly. X-ray examination by Dr. Eastmond showed stone in renal pelvis. Operation at the Jewish Hospital, Oct. 23, 1909, by the writer. Incision, 2½ inches to the right of the middle line of the back starting over the lowest rib, carried down to the crest of the ileum; exposure of the kidney, which was two and a half times as large as normal. Surface densely adherent to all the surrounding structures, due to a perinephritis. The kidney within its capsule was gradually separated from the surrounding structures and brought up into the wound. The upper half of the kidney was markedly changed and showed the effect of a chronic hydronephrosis. In some places the cortex of the kidney was so thin that it was almost like parchment. The lower pole of the kidney was not as markedly diseased as the upper pole. An incision was made through the cortex of the upper pole in the middle line and there escaped a quantity of seropurulent urine. A finger was then introduced through this opening and the calyces of the kidney were found dilated. A large, solitary, smooth uric acid calculus was found in the dilated ureter acting as a ball valve. This was easily removed.

A cigarette drain was placed draining the pelvis of the kidney, a second drain between the kidney and the peritoneum, and a short gauze drain to the kidney surface and the wound was closed. Following the operation the patient had very little disturbance. The next day he was sitting up in bed and passed 30 oz. of urine through the bladder. The second day after the operation patient felt well, was eating normally, temperature normal and pulse normal; passed 40 oz. of urine through the bladder. Considerable discharge on dressings. Third day drain was removed from kidney; condition of the wound perfect. Patient felt well, but showed inclination to sleep a great deal. Fourth day, patient very sleepy and slightly irrational. Large amount of albumin found in the urine and only a small amount of urine passed through the bladder. The temperature has been subnormal, reaching as low as 93° F. and rising again to 97°. Fifth day, only 2 oz. of urine passed; patient uremic; temperature, 86°F., temperature being taken in the axilla, in the mouth and in the rectum, by four different thermometers. Temperature remained between 85.6° and 88° for nearly twenty-four hours, and patient died.

DIFFERENTIAL DIAGNOSIS.

In tuberculosis of the kidney the early bladder involvement, with the finding of pus and tubercular bacilli, aided by cystoscopic examination, as a rule, makes the diagnosis positive. In nephralgia or neuralgia of the kidney due to congestion, hyperemia, adhesions or malpositions, the hemorrhage is usually small in amount, but is quite frequently present. In three cases of my own during the past year the hemorrhage has been microscopical, but always present. In aneurism there is present a tumor, hematuria and pain. Diagnosis is usually impossible unless there is distinct bruit and pulsation. In tuberculosis a large hemorrhage is rare.

THE TREATMENT OF HEMATURIA.

A. *If due to trauma.*

(1) Expectant treatment is indicated in the cases of slight injury, in which there is only moderate or transitory hemorrhage of short duration.

(2) Operation is contra-indicated when both kidneys are extensively injured.

(3) Operation is strongly advised when there is progressive recurrent or persistent hemorrhage, also when infection has taken place.

B. *If due to drugs or diet.*

Removal of the cause. The same treatment is indicated as in any acute inflammation of the kidney.

C. *Hematuria of disease.* In malignant fever, no treatment of the kidney lesion itself will avail. If due to nephritis, medical treatment will usually bring about a cure. If the conditions persist, decapsulation and fixation of the kidney are indicated. In rare conditions where the disease is unilateral and threatens life the kidney may be removed.

Renal varix. The treatment is based upon the pathological findings. Renal varix is a distinct

pathological entity and may be described as an angiomatous disease of the papillæ renales, whose etiology and pathology resemble that of varicocele, varicose veins of the legs, varicosities at the cardiac end of the stomach, hemorrhoidal varices, etc.

In the majority of cases, at operation, when the kidney has been bisected, no gross pathological lesions will be noted, but on microscopic examination of the papillæ renales a typical angiomatous disease will be found. Nephrotomy is the operation of choice, because it allows a thorough examination of the kidney, and also for the reason that it accomplishes exactly what the operation of multiple ligation does in the treatment of varicosities in other portions of the body, in that it cuts six of the main connecting venous radicles of the kidney and in this way destroys the varicosities.

The incision should be made along Broedel's line so as to avoid injury.

Nephrectomy is indicated only when rapid and bloodless operation is demanded, or when nephrotomy fails to relieve the hematuria.

Malignant growth requires the removal of the kidney.

Tuberculosis, removal of the ureter and kidney.

Renal stone, removal of the calculus and sometimes nephrectomy.

Nephralgia calls for renal decapsulation and the fixation of the organ.

INDIVIDUAL EFFICIENCY.*

BY FRANCIS P. EMERSON, M.D., BOSTON.

VERY early in life we reach the conclusion that we cannot accomplish much in working or playing alone. So as a natural evolution we have first our congenial friends, then our societies and finally we become identified with the larger commercial, sectarian and political groups of men who find in organization not only economy and strength, but encouragement. For the average man such association enables him to work out a larger usefulness. Instead of losing his identity, he ceases to work at cross purposes, where alone he could make no headway, and becomes an integral part of an irresistible force. This enables him to work along the line of least resistance with men of the same ideas and aims, thus multiplying his personality and increasing his efficiency. He animates what he can, and if he does not make himself felt, it is to be remembered that alone even a much stronger character would be wholly lost and inefficient. When we reach our majority, we find ourselves, by no act of our own, but by virtue of our citizenship, a part of that larger body of men which we call the government. Here again, on a larger scale, is the same idea, in that it is composed of a majority of our citizens who have united to carry out certain ideas of government, upon which they are mutually agreed. Like other organized groups of men, we find that it has a definite policy, and that one of its earliest functions was the protection of the individual. Not only in his life and liberty, but he was to be encouraged, assisted and given every opportunity to develop as an efficient member of society. Around him as a unit we have built up the common law, and his rights as a free citizen have been most zealously guarded.

From simple customs adapted to rural communities there has developed that code of laws suited to our complex social relations of to-day. At first, men united to protect the individual from attack from without, recognizing only infrequently exigencies which reminded them of their claim one upon another. But at this early time it was accepted that the foe of one was the common foe, and that no one could afford to ignore the weakness of his neighbor. As the community grew, accepted customs became incorporated into statutes, which made it the function of government to safeguard the life and liberty of each constituent member. This prerogative was at first exercised in only a few things, but gradually as society became more complex, other functions were assumed. It became necessary to protect against the vicious and lawless of their own members; to insist on certain standards of education; to insure property rights; to provide for religious observance; to guard against the spread of disease; but always on the justification that the larger opportunity and efficiency of the individual was being provided for and safeguarded. This has always been recognized as a legitimate function of associated government.

In the early history of this country, although the individual stood as the unit around which the common law was built up, he had no particular value. His cheapness was on a level with the sun, light, the rain, the land and other values that were practically free. In other words, the unit of value in commercial life has always in the history of the world raised or lowered the value of human life. As we read history we have passed through two periods and are entering upon the third wherein men's conception of life has influenced and modified all the problems of our commercial and social relations. During the first period men were largely fatalists.

If crops failed or commercial enterprises were disastrous on sea or land, it was to be borne as inevitable. Men believed either that human events were foreordained, or else sought refuge in charms, amulets and sacrifices in warding off or mitigating the wrath of evil spirits. The second period extends from the end of the first, which cannot be fixed definitely, to the beginning of the twentieth century. During this time men sought for some empirical remedy that should cure our illnesses, physical, commercial and theological. Drugs were administered for physical diseases, laws were enacted for political ills and immunity was sought for moral errors through vicarious atonements. Society was, however, becoming more complex. People were segregating in large cities. Land values had increased and individual effort was being superseded by combinations. As enterprises became larger in scope and returned richer rewards, values increased and communities

*Address delivered before American Institute of Banking, Dec. 16, 1909.

grew, the individual rose correspondingly in the scale, as an economic asset.

During this period the sciences were also developing and a better appreciation of the relation of government to the community, and the community to the individual, and of man to man, but there was no general recognition of definite underlying laws, moral, physical and commercial. With the beginning of the twentieth century men turned from empiricism to the prevention of disease, moral, physical and political, and the questions of the hour have been made to tally with this dominant idea. The new concept includes the best in the past, to which it adds a better and more far-reaching grasp of larger problems for the future. History offers no encouragement for the pessimist. The superficial observer who believes that commercial integrity is lost, that moral standards are a thing of the past, and that political life has nothing to offer an honest man, does not read aright the development of the race. It has been necessary that this new country of ours should grow, values increase, enterprises broaden and the rural population flock to our cities, in order that society as a whole should come to recognize the individual as an asset of increasing value in the community. Coincident with business competition and the rivalry of nations, man rises in the economic scale.

Communities are coming to understand the far-reaching consequences of disease and the right of each individual to be protected. They are appreciating that with the complexity of our social relations, illness, which interrupts the efficiency of an individual, affects all. It is being forced upon our attention as an economic question, and so the third period, which ushered in the twentieth century, had for its dominant concept, prevention. That is a study of the underlying laws of commerce, physical and political ills with a view to understanding their cause, how they develop, and what means can be taken, not to cure, but to prevent them. Medical science, to which associated government has looked to protect the individual from physical illness, has been an evolution like the allied sciences. Its viewpoint has changed as we have better understood our relation to natural laws. The discoveries of the chemist, the physicist, the laboratory worker and the investigator in every field of human knowledge has been drawn upon, to work out a larger concept and a richer opportunity for the individual. As we have come to understand better the relation of cause and effect, and the dependence of what had before been considered unrelated conditions, one phase of truth has been emphasized and then another, but eventually they all find their level and are added to the common fund of knowledge.

Only two hundred years ago the streets of London were breeding beds of disease. The surface of the ground was a receptacle of filth of every description. Drainage as a means of preventing disease was not practised, the water supply was polluted, sun and fresh air were excluded from the houses and the rudiments of anything like sanitary science was unknown. Everything that has since become the function of the government, the state or the municipality in safeguarding the individual has developed. Each year this regulation by law of the life of the individual for the common good is extended to include all the relations of life. Not only are we forbidden to pollute the water supply, the air, food and surface of the earth, but the height of our buildings, the hours that we shall be compelled to labor and conditions of light, air and employment of safety devices that protect the efficiency of the individual are submitted to as the prerogative of government. In addition, experts in their particular field study the laws that underlie all social relations, and as they are understood, they are added to the restrictions under which we can continue to live in safety. Individuals, rich and poor, private enterprises and public service corporations, each year expend vast sums to bring their business to conform to these regulations, that safeguard the life and property of all.

Medical science has worked hand in hand with the central authorities to further increase the efficiency of the individual by studying the origin and modes of propagation of special diseases that annually spread in epidemics over large sections of our country. In some years when the infection was particularly virulent, the loss of human life exceeded that of war. Some of these are now hardly known to the present generation. To-day our boards of health demand that every physician report all cases of typhoid, typhus and scarlet fever, diphtheria, croup, cholera, chicken-pox, cerebrospinal meningitis, smallpox, measles and tuberculosis. In another ten years it is believed that most of these will be rare. The breeding place of the infectious diseases, the public schools, has been attacked, and this year in Brighton a culture was taken from the nose and throat of every child on admission, and those infected, excluded and isolated. Sepsis which demanded its toll of thousands following surgical operations or childbirth is now a cause of explanation in the practise of any physician in even a single case. Yellow fever, cholera and malaria have ceased to carry terror and death into large sections of the country. Appendicitis or inflammation of the bowels is recognized by the recent graduate of medicine. So I might go on and enforce these assertions, by quoting statistics, to show how absolutely we have advanced in our control of these diseases, as in the case of diphtheria, where the mortality has been reduced from 20–30% to less than 5%.

Improved methods of diagnosis are in daily use. We see directly by means of the x-ray the exact condition of every joint and organ of the body. A drop of blood from the ear decides in the very beginning of illness a half dozen conditions like typhoid, malaria, etc., that mean much for the early restoration of the individual to active life. With the bronchoscope, the cystoscope, etc., direct inspection of the bronchi, stomach and all the hollow viscera can be made with certainty. Before any physical signs appear, the cutaneous

reaction for tuberculosis confirms a diagnosis of consumption before the patient is a danger to the community at large and while yet there is time to save him. Health inspectors guard the entrance of every port that we may work in safety and efficiently.

There is only one widespread disease that is a national evil, that effects youth and old age, that is seen daily in the practise of every busy man, in which we have made but little advance in safeguarding the community, and that is venereal disease. Every young man should know as his right, and be taught by those who are his natural guardians, as well as by the public, that the infection of one attack of gonorrhea may remain during life; that it is the cause of a large per cent of blindness in early life, of the necessity of abdominal operations in the first years of married life and of sterility; that syphilis is accountable for most cases of locomotor ataxia, general paralysis of the insane, many cases of apoplexy in middle life, and that the third stage may invade every organ of the body and simulate every known disease. No indulgence under any known conditions is safe, but public supervision seems so far impracticable, and only knowledge and direct instruction in early life offers any hope.

If these things are true, the same dominant idea, i. e., prevention, is working in the field of health, of politics and of commerce. Each has its natural laws of health and disease which bind us together in one common interest, — to educate the public in the prevention of associated or community ills, to enlarge the opportunity and safeguard the individual, that he may become an asset of increasing value. But after all, paternalism or a physically perfect human organism will not assure us an efficient man. The diseases which prevent our efficiency are generally not physical, but are disorders of the mind and the will. This truth, while not new or unrelated to well-known facts, is being emphasized just now, and we are hearing much of the force of habit, of the influence of mind over matter, of suggestion, etc. Remember that three fourths of human ills are preventable, and if we would regulate the functions of our body, you must do it largely from the top. Medicine or surgery only help to bring us back to right relations, and do not assure their continuance. We must keep the balance right. There comes a time when a man realizes that he cannot afford to lose his temper, be jealous or suspicious, or allow himself to lose control of himself; that his efficiency is determined by conditions under his own hat, and no man can prevent his success provided that he has the determination and is willing to pay the price.

If the signs of the times are not misleading, the efficient young man of the near future will have to start in his life work educated and made efficient to do that particular thing from the beginning. As an economic asset he is becoming too valuable to waste his time in working from the bottom up, without skilled supervision, or a wise use of his energy, whether this be in commercial or professional lines.

Medical Progress.

PROGRESS IN PHARMACOLOGY AND EXPERIMENTAL THERAPEUTICS.

BY MAURICE VEJUX TYRODE, M.D., BOSTON.

ANESTHESIA AND ANESTHETICS.

Intravenous ether and chloroform narcosis.—It was formerly the universal teaching in pharmacology that the volatile anesthetics were more suitably administered by inhalation than by other channels because by the former their effect could be more easily regulated; but Burkhardt performed a series of experiments with a view of proving that a more exact dosage could be obtained by giving the anesthetic in salt solution intravenously. For chloroform he used a saturated solution in normal saline which makes it about ½% strength by volume. By allowing this solution to run slowly into a vein he was able to obtain complete anesthesia in cats for over one hour with about 150 ccm. of salt solution containing a total quantity of 0.75 ccm. chloroform. In rabbits it took about 1.55 ccm., while in dogs about 4.70 ccm. chloroform. In all his animals there was some hemoglobin and albumin in the urine.

He anesthetized four human beings in this manner, injecting from 1100 to 1900 ccm. of salt solution saturated with chloroform (about ½%) into the medium basilic vein for about an hour. The respiration and pulse were remarkably regular from the beginning to the end and the awakening occurred very promptly after the infusion was stopped. Two of the cases, however, showed some hemoglobinuria and evidence of slight irritation of the kidneys.

He anesthetized 33 patients with a 5% solution of ether in normal saline injected intravenously, and in 30, he had no ill-effects as far as headaches, nausea, vomiting or renal irritation. In none did he see any evidence of depression of respiration or circulation.

Gianni more recently tried the method with two cases, in which one, a large angiosarcoma of the lip, and in the other a benign tumor of the hypophysis, were removed under chloroform administered intravenously in a saturated solution of normal saline. The injection was made into the saphenous vein about 4.5 cm. from its junction with the femoral. About 55 ccm. were allowed to flow into the vein during the first minute; 1100 ccm. of fluid were used in all in the first case, representing about 6.6 gm. of chloroform. The anesthesia lasted for forty minutes, and seven minutes after cessation of the infusion the patient roused. Traces of albumin were found in the urine during the day, but it was again normal by the following morning. There was no tendency to vomiting during the operation nor afterwards in either case. Muscular relaxation was complete by the fifth minute in the first case and by the fourth in the second case. In the latter, 1500 ccm. of fluid were infused, containing about 9 gm. of chloroform during the seventy-five minutes required for the operation. Patient

roused in five minutes. When the anesthesia was complete, the infusion was suspended until the corneal reflex warned that more of the chloroform was required. He does not regard the method as responsible for the slight transient changes observed in the urine of the first patient, as his previous condition was sufficient to explain it. In his research upon animals unlike Burkhardt, he was unable to observe any irritation of the kidneys. This experimenter, like the former, is very favorably impressed with the advantages and harmlessness of this technic, and especially for operations on the head and throat.

It seems to the reviewer that this method has some promise of good, because doubtlessly the regulation of anesthesia can be more accurately carried out by the intravenous (provided the solution is very dilute) than by the inhalation method. Furthermore, there is the distinct advantage of not administering or passing through the body of an individual a greater quantity of anesthetic than is absolutely necessary for complete anesthesia. The local irritation of the air passages and of the stomach (swallowing of ether-laden mucus) by the inhalation method or of the colon, sigmoid and rectum by the rectal method is entirely avoided. Yet, it must not be forgotten that both ether and chloroform have the power of precipitating proteids and of disintegrating the red blood corpuscles (hemolysis); thus by too rapid direct injection into the circulation we incur some danger of embolism or thrombosis besides the general liability of infection following intravenous administration. From the experiments in animals we might also be led to consider whether the irritant action of the anesthetic is not greater upon the kidneys when given intravenously.

Rectal anesthesia.—Since Pirogoff first introduced rectal anesthesia it was tried by a number of surgeons, but never received really serious attention until Cunningham introduced an improved method of rectal ether administration which corrected to a great extent the marked diarrhea and dysentery which previously followed such anesthesia. Since Cunningham's report a number of European surgeons have taken up his method and reported statistics upon it, as Baun, Dumont, Kadjian, Morosow quotes the latter's result in five years. He operated on 68 cases with rectal anesthesia, and in 61 the patient slept perfectly well, in 5 they were restless and in 2 they did not sleep at all. Vomiting during narcosis occurred three times, bloody diarrhea in 6 cases, while common diarrhea in 3, accompanied by cramps. In the remaining 59 cases no bad effects whatever followed.

More recently, a case reported in the JOURNAL of a sailor who received rectal ether to allow the removal of an epithelioma about the mouth. He died in a few days after operation and at autopsy it was found that he had chronic dysentery and that an ulcer had broken during the anesthesia and caused general peritonitis.

The reviewer believes that although rectal anesthesia has a field of usefulness, especially in face operations, yet it should never be employed when there is any disease of the intestines, and in fact its use should always be preceded by a careful physical examination of the abdomen, analysis of the feecs and an examination with sigmoidoscope.

Anesthesia and diuresis.—Hawk has pointed out that marked diuresis occurs during etherization, beginning after thirty minutes and continuing for four and a half hours. This is probably to be explained by the direct stimulation of the kidneys by ether plus the dilatation of the renal blood vessels.

Fleig performed some experiments in which he tested the value of artificially increasing diuresis after anesthesia and also of counteracting hemorhage by rendering the blood more readily coagulable. He reports a research which demonstrates that the heart's action can be reinforced, the blood pressure increased and coagulation promoted by preventive injection before the operation of an isotonic solution of calcium chloride with or without a mixture of blood serum. He shows also that elimination of the anesthetic is promoted and the period of its contact with the tissues shortened by the subcutaneous intramuscular or intravenous injections of solutions of glucose or levulose. Copious diuresis is induced by these injections which wash out the anesthetic and attenuate its secondary toxic effect, while they have besides a tonic action on the cardiovascular system, combating reduction of blood pressure and collapse. The sugar solution has also a certain nourishing action. The sugar and calcium chloride may both be combined in a single solution. He urges that more general adoption of such measures, especially in chloroform anesthesia and when there is reason to dread an injurious action on the heart. He warns, however, that the calcium chloride or blood serum should never be used in cases in which there is danger of thrombosis.

He shows that these glucose injections shorten greatly the post-operative anesthesia. In one dog diuresis became copious in ten minutes after injections of 4.40 ccm. of 25% glucose solution and continued thus for twenty minutes, after which the dog roused, while the same animal three weeks before did not rouse for one hour and a half after the administration of the same amount of chloroform. Hypertonic solutions of sugar ingested by mouth do not seem to have the slightest diuretic action, and diuresis is less with isotonic solutions ingested by mouth than when pure water is taken.

It is not at all surprising that Fleig could not obtain diuresis in normal individuals by the taking of sugar internally because the liver takes care of it before it can reach the general circulation.

Narcosis and adrenalin mobilization. — Schur and Wiesel found out experimentally that the chromafin affinity of the suprarenal and sympathetic system is decreased by narcosis (ether, chloroform, etc.) and is altogether suspended if anesthesia lasts from three to five hours. At the same time extracts of the suprarenals of such animals failed to dilate the frog's pupil or to raise the blood

pressure or to give the iron-chloride reaction. Therefore, there is a pouring out of adrenalin into the circulation during narcosis since, contrary to the serum of the normal rabbit, that of the anesthetized has a mydriatic effect after one or two hours which disappears after a longer time. Then a few hours after narcosis is interrupted the chromafin reaction begins to reappear and reaches its normal intensity in eight to twelve hours. It is interesting to note that fatalities during anesthesia are more frequent in lymphatic individuals with hyperplasia of adrenalin-containing tissues and is probably explained by the sudden liberation of too large quantities of adrenalin.

These observations are exceedingly interesting as they are capable of explaining some of the heretofore unexplainable surgical shocks as acute adrenalin poisoning.

Effect of anesthetics on the bactericidal power of the blood. — Zimine found that in guinea-pigs the englobement by the phagocytes of the bacillus proteus injected into the peritoneum is much less active in the pigs which have been etherized from forty-five minutes to two and one half hours than in normal pigs or those subjected to chloroform.

Graham, after an exhaustive study, confirmed the work of the preceding and found great reduction in phagocytic activity against the streptococcus, staphylococcus, bacillus coli and typhosi after etherization. This author likened the results to those obtained by others after alcohol and chloroform and adopts the Mayer-Overton theory of anesthetics dependent on mechanical affinity for fatlike substances to explain the condition. He seems to prove the point by showing a restoration of phagocytic activity after it has been lowered with ether by the administration of lecithin or fats, as olive oil. Not only does he get results by subcutaneous administration, but also by rectal injections. This is exceedingly interesting, for if fats restore phargocytic activity after its diminution by anesthetics, it is possible that they may restore it after it is lowered from other causes, and thus the forced feeling in tuberculosis with large amounts of fat may have its good result partly by neutralizing the toxins which lower the phagocytic activities of the serum.

This also suggests that the shorter the operation and the smaller the quantity of anesthetic given, the better are the chances of avoiding infection. This was remarkably proved in our laboratory some years ago when dogs operated for gastric fistula, by some research men with poor technic prolonging the operation from an hour and a half to two hours, yet under the strictest aseptic and antiseptic precautions, all died of sepsis. On the other hand, two dogs operated without antiseptic precaution, mere cleanliness, but the total operation lasting less than ten minutes, no sepsis occurred in either case.

These facts would seem to indicate that besides shortening an operation and quantity of anesthetic to its lowest minimum, patients who have been subjected to an operation should be fed with more care, increasing as rapidly as possible the easily digestible fats in the diet.

General pharmacological action of ether. — After an exhaustive and painstaking research, Draux comes to a very interesting series of conclusions which follow:

1. Ether injected subcutaneously in normal dogs is capable of causing a slight rise of blood pressure and increased pulse rate.

2. Ether injected intravenously causes at first a lowering of the blood pressure, soon followed by a certain rise. The fall of pressure is accompanied by a diminution of the amplitude of pulsation and often by slowing of pulse-rate. The rise of pressure is frequently accompanied by an acceleration.

3. The slowing which follows the fall of pressure after intravenous injections of large doses of ether is the result of reflex irritation of the vagus.

4. Ether produces a depressant action on the isolated heart which manifests itself by a diminution in the amplitude of the pulse waves, by a slowing of the rate going to complete stoppage and by irregularities in the rhythm.

5. The fall of blood pressure observed at the beginning of intravenous injection is not due to a vaso-dilatation, but to a direct depressant action on the heart. The oncometer tracings of the kidney, spleen and paw, instead of showing a rise, as in vaso-dilatation, show, on the contrary, a fall which is most marked when the dose of ether is greatest.

6. The rise of blood pressure in etherization is due to vaso-constriction and not to stimulation of the heart.

It is interesting to note that this author definitely proves the depressant action of ether on the heart from the beginning without any stimulant stage, a point which has been held for so many years by pharmacologists, but so much contradicted by many clinical men on account of wrong observations. He shows that the rise in blood pressure which sometimes occurs is not evidence of heart stimulation, but only of vasomotor constriction.

Nicloux proves that inhaled ether is excreted by the milk, and this he explained by the fat contents of this secretion which attracts ether.

Toxicity of chloroform. — Doyen, Gauthier and Policard, in a recent work, found that chloroform taken by inhalation produces in dogs an excretion of pathological urobilin which they believe comes from the blood; also they think that it has some relation to the hepatic lesions. These facts are in harmony with the observations of Hamberg and Ewing, who found marked anemia after chloroformization, and also an increase in the hemolysis of the blood. Of course the degeneration of the liver and also the acid intoxication which has some relation to the former have been described by numerous authors with citation of cases. A particularly good review is given by Wells.

Fate of chloroform in the body. — It was formerly taught that both ether and chloroform left the body intact without undergoing any chemical changes, but Nicloux in a recent paper adduced evidence to show that a certain portion of inhaled chloro-

form which is not recovered in the excretion is changed by a process of hydration with the ultimate formation of carbon monoxide.

Nitrous oxide and oxygen anesthesia. — Since the anesthetic action of this gas was discovered by Wells in 1844, and brought into general dental use for extracting teeth by Colton in 1863, it was not employed as a general anesthetic until Andrews, of Chicago, in 1868, showed such possibilities by using nitrous oxide and oxygen combined. Paul Bert, in 1880, worked extensively with this combination and proved conclusively its practical application in surgery. Yet since that time up to recently nitrous oxide has been but little employed with oxygen as a general anesthetic. One of the main objections was that it was believed that it could only be administered under artificially increased atmospheric pressure, which necessitated very cumbersome apparatuses, pneumatic cabinets, etc. Later, however, very much simpler apparatus has been devised, so that one of the main objections has been overcome.

Bevan, of Chicago, has again brought up the subject in America a few years ago and reported many successful major surgical operations performed under nitrous oxide and oxygen mixture. More recently Peairs, Teter and Crile write most enthusiastic reports from its use. Peairs' new apparatus is simple and easily portable, weighing only 19 lb. Teter has administered the gas thirteen thousand times, and one thousand times in major surgical operations. Crile used it in five hundred and seventy-five major operations. He compares it very favorably to ether, stating that nausea occurred in 17% of cases as compared with 42% under ether. He believes that, just as with ether, nausea from nitrous oxide is due to uneven administration. He is particularly gratified by the rapid recovery of the patient to the unclouded possession of all his faculties, also the great diminution of surgical shock and the more rapid return of the pulse to normal after operation. In fact, he strongly recommends it especially in the so-called handicapped cases which would make a bad ether anesthetic risk.

In spite of the favorable reports there are some unfavorable features to this mode of anesthesia, and one is that it is sometimes impossible to obtain absolute muscular relaxation. Hilliard's study on the influence of the barometric pressure probably explains many of these cases, as when the barometric pressure is low it is impossible to get absolute surgical anesthesia without dangerous cyanosis. Furthermore, it is a fact that the blood pressure is considerably raised and, therefore, it is dangerous to use this method in atheromatous conditions or in individuals having the entiological antecedents of these as excess of alcohol and tobacco.

Spinal and local anesthetic of the cocaine group.— On account of the widespread interest of spinal anesthesia during the last few years, it is interesting to note an article from the laboratory of Professor Reclus by Piquand and Dreyfus on the comparative anesthetic power and also toxicity of cocaine and its substitutes. The different local anesthetics or combinations thereof are classified as follows with decreasing strength:

1. Cocaine.
2. Novocain-adrenalin. (Analgesic power not far from that of cocaine.)
3. Novocaine, alypin, coca-stovaine (the three have about the same anesthetic power except that the effect of novocaine is less lasting).
4. Stovaine, tropacocaine, beta-eucaine. (These three have about equal power.)

As regards the toxic action determined by intravenous injections in rabbits, the following results were obtained with decreasing toxicity downwards.

Fatal dose per kilo.	Name of drug or combination.
0.017	Alypin
0.0183	Cocaine
0.019	Beta-eucaine
0.02	Tropacocaine
0.027	Stovaine and cocaine equal parts
0.03	Stovaine
0.046	Novocain-adrenalin
0.063	Novocaine

As may be seen by these tables, the novocain-adrenalin is the most active and next to the least toxic and, indeed, it is this anesthetic which Reclus has found the most valuable. They cite three cases of inflammatory and gangrenous conditions following the anesthetic, but they attribute it to some probable mistake in sterilization, etc., as Reclus has had 700 cases without any accidents following.

It would be a strong endorsement for novocaine spinal anesthesia if cases of death and paralysis by this method had not been reported, besides occasionally very intense untoward effects. Thus Gabbet reports the death of a patient from evident paralysis of respiration while removing an elephantiasis of the scrotum. As Gabbet had given 1 mgm. or 1-60 gr. of strychnine to his patient, he concluded that death had occurred from strychnine poisoning because there was stiffness of the arms, which, of course, could easily be due to the asphyxia incident to the paralysis of the respiratory center by novocaine.

Such a dose of strychnine could not possibly produce death, and from the description of the symptoms the reviewer has no doubt that death was due to the 1–10 gm. of novocaine given.

Furthermore, Spielmeyer, in a research on this local anesthetic, was able to show marked neurohistological degenerations, particularly in the motor-ganglion cells of the anterior horn. Such changes would, of course, explain the occurrence of paralysis. Spielmeyer had previously found these lesions after stovain. He claimed that, these could not be seen with a dose less than 0.07 but Hardouin records one case of death in ten patients from a dose not exceeding that. Santesson after a careful research upon the action of cocaine and stovaine on nervous fibers found that the latter produced changes in the myelin of the nerves. With the well-known paralyzing action of all these substances on the respiratory center, it is difficult to understand the results claimed by Jonnesco and Jiano, who inject these

drugs in the cervical cord and even within the skull after trepanation. Concerning stovain, Munchmeyer's report of 1,000 cases is rather interesting. He claims 70% without ill-effects, 30% chiefly with headaches, 7 cases of motor paralysis, lasting from eleven to fourteen days, including 5 of the limbs and 2 of the abducens.

It seems to the reviewer that spinal anesthesia is a decidedly more dangerous method than most of the others previously mentioned in view of the fact that none of the local anesthetics so far are devoid of very toxic effects in doses necessary for anesthesia. The danger of paralysis has to be seriously considered on account of degenerative changes which they may all produce in the spinal cord. Some authors report as severe if not more severe post-operative discomforts than after ether, as nausea, vomiting, headaches, etc. Furthermore, even if we had a perfect spinal anesthetic devoid of toxicity (which we do not have as yet), the method would be objectionable on account of the consciousness of the patient during the operation, which is liable to produce a great deal of psychic shock, much more than would occur when unconsciousness is preserved throughout the operation.

New Feature of Hopkins Medical Clinic.—A "heart station" will be instituted at the medical clinic of Johns Hopkins Hospital next fall. It will be equipped with a special laboratory for examining the heart by electricity and other new graphic methods of registration.—*Jour. Am. Med. Asso.*

Reports of Societies.

THE AMERICAN NEUROLOGICAL ASSOCIATION.

Thirty-sixth Annual Meeting.

May 2, 3 and 4, 1910.

Monday Session.

The Association was called to order in the Yellow Room of the New Willard Hotel, Washington, D. C., at 2.30 P.M. by the President, Dr. Morton Prince, of Boston, who delivered an address entitled,

CEREBRAL LOCALIZATION FROM THE POINT OF VIEW OF FUNCTION AND SYMPTOMS WITH SPECIAL REFERENCE TO VON MONAKOW'S THEORY OF DIASCHISIS.

Dr. Morton Prince, of Boston: I have chosen as a subject upon which to address you that of the doctrine of cerebral localization from the point of view of function and symptoms. The doctrine of cerebral localization acquires a very different significance according as to whether it means that the brain can be mapped out into a number of circumscribed areas, in each of which can be located a definite psycho-physiological faculty or function, or whether it means only that these areas contain anatomical elements which are made use of for the physiological expression of function. The doctrine of cerebral localization resolves itself into the question whether the localization is of symptoms or of function, or whether it is only an anatomical localization of fibers. It too often happens that the formulæ of localization do not work in diagnosis. It not rarely happens that clinical and pathological findings are contradictory. Thus, on the one hand, extensive lesions in one or another of the recognized cortical centers run their course without symptoms, and, on the other hand, focal symptoms, pointing to disease of these centers, develop in cases in which no anatomical alterations are found at autopsy.

There is a growing dissatisfaction with the currently accepted doctrine of cerebral localization; a feeling that it is in many respects inadequate. The first blow to the traditional localization of function in the cortex was received when Marie launched his attack on the currently accepted doctrine of aphasia. Whatever the outcome of the reinvestigation of this question shall prove to be, it is evident that the beautifully diagrammatic concepts of the function of language and of aphasic disturbances of this function have been relegated to the scrap heap of the phantasies of science. Our former naive conception of aphasia can never be revived. The fact, I believe, will be found to be that whether the third left frontal convolution, the first and second left temporal convolution or other areas take part in the function of language or not, the function as a whole, as a psychical process, is a widely distributed one in which are engaged many dynamic processes and anatomical "centers," and a lesion of any one of several "centers" may give rise to all modes of apahsic disturbance. The contest has centered largely around the question whether a lesion of Broca's convolution gives rise to the motor type of aphasia and, therefore, whether in this convolution can be localized so much of language as is lost in this type. In thus stating the problem there is plainly a confusion of concepts; the one is a clinico-anatomical question involving a particular syndrome, the other a question of localization of function. In distinguishing between these concepts perhaps the difficulties may disappear, for a lesion might theoretically give rise indirectly to a group of language symptoms without being the seat of language function.

The clinico-anatomical data themselves are contradictory. As, for example, (1) Lesions of F3 do give rise to a clinical aphasic syndrome of the so-called motor type. (2) Destruction of Broca's convolution may be accompanied by simple mutism, or pure motor aphasia of the so-called subcortical type. (3) It also appears to be true that in a considerable proportion of cases of aphasia, characterized by loss of the power of word-formation and articulation, Broca's convolution has been found intact. In any theory of aphasia as a clinical syndrome, and in any theory of function, these discrepancies must be reconciled. May it not be that a lesion in F3 may occasion a disturbance of language of the so-called motor type and yet this convolution not be an essential factor in the functioning mechanism of language? If time had permitted, other syndromes and functions might have been taken for analysis; for example, astereognosis, asymbolia, apraxia, in which similar contradictions would be found.

Von Monakow, whose clinical experience and pathological training entitle his views to great weight, points out the inadequacy of the generally accepted doctrine of localization to account for these contradictory phenomena. He believes that there lies some error in the form in which localization is conceived by most clinicians. To-day, as formerly, two sets of experiences stand opposed to one another, the negative and the positive, and invite anew discussion of the doctrine of localization, which has been declared closed by many writers. We must ask how these contradictions can be explained. To answer this Von Monakow proposes a theory, which is of the greatest interest and challenges examination, known as diaschisis, and which has for its basis the results of experimental investigation. After removal of focal areas in the cortex, certain symptoms are temporary, while others, which are purely local, are permanent. These latter or residual symptoms alone represent the function or part of function that is localizable in a given center. So-called focal symptoms are in large part a complicated reaction of unimpaired areas of the central nervous system to the local cortical lesions. By diaschisis is meant a functional shock-like inhibition of previously uninjured distant areas produced by the dynamic influences of a lesion anatomically connected with such areas. Through the break in the continuity of the conducting associative paths the eccentrically lying brain foci are robbed of their natural sources of stimulation and in part isolated. Only the directly injured elements give rise to the permanent symptoms and secondary degerenations.

So far as the theory definitely distinguishes between the localization of symptoms and the localization of function, I think it may be safely insisted upon as the only interpretation that can reconcile the facts of clinical and pathological observation. The diaschisis theory is fruitful in other fields than that of cerebral localization. For example, its possible applications in the explanation of focal symptoms without focal lesions will occur to every one.

A REPORT OF THREE PRE-FRONTAL TUMORS.

DR. F. X. DERCUM, Philadelphia: First and second, inoperable; third removed, but of enormous size, weighing 7¾ oz. Death fourteen days after operation. Report of operation and subsequent surgical history by Dr. John H. Gibbon.

The symptoms present in the above cases are of unusual interest. Vague mental symptoms were present in all of them. Case I suggested symptoms not unlike those of profound cerebral exhaustion of a beginning paresis. Headache had never been a marked feature, and was elicited only by questioning. It existed only for a short time previous to death; vomiting occurred but once and that only toward the very close of the illness. There was absence of optic neuritis and any involvement of the visual fields. The only symptom which was at all suggestive was one attack of slight twitching of the left leg and possibly twitching of the left arm, which occurred a few days before he came under observation; the attack was very brief in duration and was not attended by loss of consciousness. Occasionally psychic vesical incontinence was present.

In the second case there was early headache, optic neuritis and vomiting, all of the symptoms being typical and marked. The feature of special interest is the slight flattening of the lower half of the right side of the face and the equally slight involvement of the left leg and arm. These symptoms were in all probability due, in part at least, to indirect pressure. The subjective sensory disturbances in the left leg and left arm, namely, pain and the hyperesthesia of the left arm and both legs, are somewhat difficult to explain. The occurrence of typical areas of hysterical painful hyperesthesia under both breasts and over both groins is exceedingly interesting and important and must be borne in mind in considering the other sensory symptoms present. The area of hyperesthesia upon the left parietal region was also small and resembled in other respects an area of hysterical hyperesthesia, though it was present on the same side as the tumor; the question arises whether the left hemiparesis, present for a time only, was not also hysterical in origin.

In Case III, optic neuritis was pronounced. Headache was scarcely, if at all, present. Vomiting was absent. Case III, is remarkable for the size of the growth, which had probably existed for a long time previous to the seizure, which occurred in the summer of 1908. That so large a growth could have been present and the patient still have been able, even in a degree, to attend to his business and ordinary affairs is very remarkable. Finally, the resemblance of the mental symptoms in Cases I and III to those of paresis is worthy of comment. Case I was placid, indifferent and did not manifest the least anxiety as to his condition. Case III was at times distinctly expansive, good-humored and not infrequently laughed and joked. Case II, though quiet, complained greatly at times of suffering; at no time was she jocose, nor was there any tendency to laughter or hilarity. Indifference to the sphincters was not observed and there were no epileptiform seizures. The eye muscle symptoms made their appearance late and are probably to be referred directly to the frontal lobe lesion; in part they may have been due to the blindness and the absence of fixation.

In many respects the above cases conformed to the ordinary observations made in prefrontal tumors. This was particularly the case as regards the mental symptoms, which were most marked in Case III, less marked in Case I and least in Case II. Psychic incontinence was pronounced in Cases I and III. Epileptiform seizures were present but once in Cases I and III, and absent altogether in Case II. Optic neuritis was present in Cases II and III, and absent in Case I; the swelling was more marked on the side of the tumor in Case II, and slightly greater on the side opposite the tumor in Case III. Local tenderness of the skull was present only in Case II, was on the same side as the tumor, but was parietal and not frontal.

Finally, it is interesting to note that in none of the cases was there present any ataxia.

It should be added that no x-ray examination was made in Case I. In Case II an x-ray examination was negative. Case III an x-ray examination was

also negative save that it revealed some irregularity of the inner surface of the frontal bone upon the right side; also some apparent thinning of the bone. The possible etiological value of trauma is well illustrated in Case I.

DISCUSSION.

Dr. E. W. Taylor, of Boston: The two main points that Dr. Dercum has brought out are of much interest. In the first place, the mental condition; in the second place, the epileptiform seizures. From what Dr. Dercum has said, and I presume it is generally accepted, there is no definite type of mental disease in connection with frontal lobe lesion. I recall distinctly a patient in which the mental symptoms, instead of being apathetic, were precisely of the opposite sort. The man was a young army officer, previously healthy. He was extraordinarily apprehensive; he developed all sorts of phobias, was unable to go into crowded places, buildings and so on, and presented all the appearances of a psychasthenia. He had slight epileptiform convulsions which I misinterpreted as hysteroid convulsions. He disappeared from view, and, if I had not heard his subsequent history, I would have regarded him as a psychasthenia patient. He later developed definite signs of brain tumor and died. There was found an extensive pre-frontal tumor, gliomatous in type, very difficult to distinguish from the brain itself. The points of importance in this case were incidence of slight seizures, epileptiform in character, and, secondly, and still more confusing, were a series of symptoms, which one so often sees in the neuroses of psychasthenic character, and which were benefited by mental treatment.

Dr. Edward B. Angell, Rochester, N. Y.: I have been impressed with the lack of symptomatology of prefontal tumors. We get many of these cases without headache, nausea, vomiting, without any of the motor symptoms and without any of the hemiplegias or disturbances of one side of the body. A case came under my observation one year ago; a very successful and intelligent business man. He suddenly became apathetic; his family first noticed this because he received news of a disaster with unconcern. Aside from that condition he had no symptoms whatever. He had an attack of grippe and had quite a nasal discharge and quite an increase in the white blood cells. Here was a case where we had reason for believing we had acute trouble by extension from the nasal chambers. The mental symptoms were not such as to indicate much pressure. When he died, and it was shortly, he had a tumor as large as Dr. Dercum's patient in the left prefontal lobe.

Dr. Hugh T. Patrick, Chicago: What was the state of the sense of smell in these cases?

Dr. Herman H. Hope, Cincinnati: I wish briefly to refer to one symptom-complex which obscured the diagnosis in a case seen in which there were absolutely no general symptoms of brain tumor. This tumor grew from the sella turcica and involved both portions of the frontal lobes. The earliest manifestations were in reference to the optic thalamus. This man went on with business after developing atrophy of the optic nerve; then he began to develop sluggishness of the pupils. In the subsequent history there was a pure simple dementia, so much so that the diagnosis of dementia paralytica was made. The man died in an insane hospital and the autopsy revealed the tumor.

Dr. George Jacoby, New York City: I had the pleasure and benefit of seeing the case Dr. Dercum has reported, and, after seeing that case and comparing it with a couple of others I had previously seen, it seems to me that we can be very positive that there is no pathognomonic series of symptoms of prefrontal tumors. One way diagnosis can be made is by sequence of symptoms or symptoms dependent upon pressure; the occurrence of aphasia and involvement of the motor tract, the significance of reflexes, all of which are helpful and indicative of the associated pressure.

Dr. E. E. Southard, Boston: I have found that in some cases it is profitable to examine histologically other parts of the brain than those directly involved in the tumor. I recall a case of tumor of the prefrontal lobe in which epilepsy did not exist, but in which there was a unilateral paralysis on the same side as the tumor, and histological study of the precentral gyri showed that for some reason on the opposite side there was absence of cells.

Dr. B. Sachs, New York City: In regard to frontal tumors, I do not know why they were spoken of as prefrontal tumors. There were two points of vital importance in regard to the question of operability: First of all, the focal signs, as in many instances they give no idea of the actual size of the tumor and the probable result of an operation. So much depends upon shock—the shock seems to be in direct proportion to the size of the tumor,—that one of the most essential points for determining the operability of a tumor is to try to decide whether the tumor is of large size or not and whether the symptoms give one any idea of the size of the tumor. The other points belong to all tumors. A great deal depends upon the character of the tumor, particularly in the development of symptoms. It is a very different thing when the brain substance is being invaded by tubercle or sarcoma or whether it is being gradually invaded by a glioma, and some of the peculiarities in regard to tumor of the frontal lobe may be explained by the fact that many of these tumors have been slowly invading gliomata, whereas the cases in which the tumor has been much more destructive, the symptoms are more marked. The destructiveness of the tumor is in direct relation to the distinctness of the symptoms. I have observed a case which had presented during life absolutely nothing else but epileptiform seizures which suddenly died from hemorrhage from a tumor, which on post-mortem examination proved to be a huge glioma involving one entire hemisphere of the brain. This is a point we often lose sight of, that is, the different character of the symptoms in relation to different structure of the tumor. Glioma seems to cause fewer symptoms than any other tumor because the brain tissue accommodates itself much more readily to the slow invasion of the glioma.

Dr. D. D. Wolfstein, of Cincinnati: I wish to refer to a case in which I made the diagnosis of tumor of the frontal lobe. It was in the left frontal lobe, and of very large size, but there was absolutely no mental disturbance. The only symptoms were progressive optic atrophy with complete loss of vision. There was a suspicion of epileptiform seizure. Very often these tumors pass far back and tangental fibers which pass through the capsule are involved. Those cases which simulate epileptiform seizures might in this way be explained.

Dr. Dercum, closing: In these cases the sense of smell was preserved. In a case which I reported to the Association some years ago the sense of smell was destroyed. I think Dr. Southard's position well taken. It seems to me that the epileptiform attacks in these cases were perhaps due to pressure about the base. I am in entire accord with what Dr. Sachs has said in reference to the size of the tumor. The first two cases were round-celled sarcomata, the third was endotheliomata and sprang from the dura of the base. As regards the term "prefontal" I feel that it

is a justifiable term, provided we strictly mean that the tumor has advanced up in front of the motor tract itself.

REPORT OF A CASE OF RESECTION OF DORSAL SPINAL NERVE ROOTS FOR GASTRIC CRISES OF TABES.

DR. JOHN JENKS THOMAS and DR. EDWARD HALL NICHOLS, of Boston: Writers agree that the gastric crises of tabes are of nervous origin, and may be very severe and lead to death. The attacks not infrequently constitute the earliest symptom of the disease. This fact has frequently led to error of diagnosis and the performance of useless operations. Post-mortem in fatal cases, the stomach usually shows no changes, even when blood has been vomited. The most probable theory as to causation is that the pathological basis consists in changes in the sympathetic nerves. This view was adopted by Förster and led him to resect the dorsal thoracic nerve roots, by which the sympathetic nerves are connected with the central nervous system. Aside from this first case of resection of dorsal nerve roots for this symptom reported by Förster and Küttner, one other case has been found in the literature, reported by Brüns and Sauerbach, both operations having been done in the summer of 1909 and both followed by complete relief.

The patient whose case is reported in this paper was a man of thirty-two years, a widower, with one healthy child, a girl of thirteen. This child was followed by three or four miscarriages of unknown cause. Syphilis was denied. The gastric crises began about eight years before, and in October, 1905, the abdomen was opened at a hospital, but nothing abnormal was found except a few adhesions of the omentum to the gall bladder, which did not pull upon the stomach. These adhesions were freed. The attacks continued and he entered the Boston City Hospital, Aug. 3, 1908; at that time his attacks came at intervals of one week to one month, and lasted from one to ten days with severe pain and vomiting, accompanied usually by diarrhea. There had been no loss of control of the bladder, but some diminution of sexual desire. No lancinating pains, no diplopia and no ataxia in walking or standing, but very slight ataxia in movements of legs with eyes closed. Hypertonicity in legs well marked. Pupils moderate size, regular and equal, reacting with accommodation, but not to light. Patellar and Achilles reflexes equal and present. At this time he had become habituated to the use of morphine and was taking about a grain a day. The attacks continued, gradually becoming more frequent, seldom a week passing without one. In August, 1909, the Noguchi serum test for syphilis was positive. At the time of operation the weight, formerly 145 lb. had fallen to 100 lb., sensation for touch and pain was diminished on the chest from the third to fifth rib and the abdominal reflexes were lively. The left Achilles jerk had disappeared though the right one and the patellar reflexes were present. March 3, 1900, the seventh, eighth and tenth thoracic dorsal roots were cut. After the operation there was severe twitching of the abdominal muscles at times and pain about the chest, which gradually diminished. He vomited once while still in the hospital after being given mercury by mouth and once after his discharge after eating beans, but neither time was there any pain, nor was the vomiting persistent, being over within an hour. There was the same condition on examination, but an absolute loss of the sense of touch and pain from the level of the sixth rib to three fingers' breadth above the umbilicus, and from this area no abdominal reflex could be obtained, but it was present and increased on irritating the skin of the lower abdomen. The man regarded himself as cured of his crises, but had not gained in weight and was attempting to diminish his morphine and had reduced it to two quarters of a grain a day.

(To be continued.)

Book Reviews.

Nutrition and Dietetics: A Manual for Students of Medicine, for Trained Nurses, and for Dietitians in Hospitals and Other Institutions. By WINFIELD S. HALL, Ph.D., M.D. New York and London: D. Appleton & Co. 1910.

These two volumes are complementary. The former, a second edition of Lusk's well-known work, aims to review, in fairly technical and scientific manner, the experimental data on which rests our knowledge of nutrition in health and in disease. The latter, a new publication, undertakes to present in more practical, didactic form, for medical students, nurses and general practitioners, the details and methods of application of this knowledge to the actual, specific problems of dietetics. Each is admirable in its particular field. Lusk's new edition brings up to date a textbook of standard value and convenient reference, especially for investigators in the physiology and pathology of metabolism. Hall's book, presenting as it does the result of the author's experience in teaching nutrition and dietetics, should meet the definite need of a less technical manual on these subjects. Both volumes are well arranged and adequately illustrated.

The Family Health. By MYER SOLIS-COHEN, M.D. Philadelphia: The Penn Publishing Company. 1910.

This volume aims to present in simple form the principal details of domestic hygiene, and succeeds well in its attempt. The several subjects are classified under appropriate chapter headings, and the topics considered in each are clearly arranged and expressed. The book should have a wide and deserved popularity in this age of popular interest in health and its maintenance.

Dose-Book and Manual of Prescription Writing. By E. Q. THORNTON, M.D., Ph.G., Assistant Professor of Materia Medica, Jefferson Medical College of Philadelphia. Fourth edition. W. B. Saunders Company. 1909.

This manual now in its fourth edition contains much useful information which has been brought abreast of the changing conditions of practice. Certain portions have been entirely rewritten, notably the table dealing with solubilities. The chapters dealing with solvents and incompatibilities, preparations and methods of prescribing them have been amplified. The general form and appearance of the book is the same. It is excellently printed and bound in flexible covers.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JULY 7, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 806 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 Tremont Street, Boston, Mass.

THE ANTI-VIVISECTION AGITATION.

Massachusetts has this year been free from the usual legislative activity regarding the regulation of vivisection. New York has not fared so happily in this respect. Although not very much has been accomplished by the opponents of vivisection as yet, their activity apparently continues unabated, and it is felt that although adjournment of the legislature has taken place, it is still necessary to carry on the campaign against the anti-vivisection faction.

The Medical Society of the State of New York has undertaken this work and has circulated a vigorous statement which should have a wide reading outside of the particular state involved. It is evident that legislation directed against the practise of vivisection, should it become law in any individual state, must have a wide influence on legislative bodies in other parts of the country. It is therefore desirable that the country at large unite in a protest against such legislation if it appears particularly imminent in any one locality.

For several years the anti-vivisection societies of New York have introduced into the state legislature bills which, if enacted, would interfere materially with teaching in medical schools and particularly with investigation. In spite of the fact that these efforts have up to this time entirely failed, it is unwise for the profession to grow lax in its opposition on this account.

The anti-vivisectionists failing thus far in convincing legislatures of the justice of their position have undertaken a propaganda in every respect pernicious by establishing in certain places exhibits which purport to represent the facts on vivisection. Such exhibits have appeared in New York City during the past winter, and it is stated that the Anti-vivisection Society of New York now proposes to carry its exhibit to various county and agricultural fairs to be held during the autumn, in the hope thereby of influencing the legislature, through which alone their ultimate objects can be secured. The unfairness of this method of attack must be evident to all right-feeling persons. The exhibit naturally appeals to the prejudices and to the uncultivated feelings of the masses, and thereby excites a sentiment which undoubtedly, if sufficiently widely exploited, might have a very distinct influence on popular opinion. That these exhibits, representing a stuffed animal, for example, in an uncomfortable position on a board with no statement regarding anesthesia, are essential misrepresentations of the facts needs no comment here. The point of importance is that such appeals to an ignorant public opinion are pernicious and misleading and should be prevented in the interest of decency and good taste. We hope that means may be found to avoid such an unfortunate appeal to the morbid curiosity of the crowd.

In an open letter to the New York Times by Professor F. S. Lee, of Columbia University, discussing this question of anti-vivisection exhibitions, an excellent statement is made of the methods employed, two paragraphs of which we quote:

"A significant part of the exhibition consists of the tales that are told to the visitors by the women attendants. Of the various operations that are portrayed or suggested, one is frequently told that they are customarily performed without anesthetics, a statement which is not true. One attendant said to a visitor that the surgical head-holders were used for the purpose of breaking the jaws of dogs, and that this was done without anesthetics. When questioned as to the reason for breaking the jaws of dogs she confessed ignorance. Such a procedure is so patently fantastic as to render comment unnecessary. There is an oven, heated by gas burners which contains the stuffed body of a rabbit, and which the attendant tells you is used for the purpose of baking live animals to death, and that this also is performed without anesthetics. Fabrication and grotesqueness here reach their culmination, for the oven is an apparatus intended for the incineration of dead organic matter, the anatomical refuse of a laboratory. The attendants are ever ready to discuss animal experimentation, seemingly quite unaware of their great and prejudiced ignorance. They do not

hesitate to speak of well-known and highly respected scientific men in intemperate language that is anything but refined or parliamentary."

"In the exhibition of which I write the most striking single exhibit is the New York Anti-Vivisection Society itself. It has had every opportunity to learn the truth or the falsity of its demonstrations and its declarations. It has been told by those who know how untrue they are, and yet it has continued week after week to keep its deceptive sights before the public and to tell its false tales. In the minds of those who both know and respect the truth the New York Anti-Vivisection Society stands, under the deceitful mask of a pretended moral leader, as an obscurantist, a partisan of vicious principles and practises, and a foe of the public good."

AN IMPORTANT CHARITY.

AN appeal for aid which should not be in vain is that of the Milk and Baby Hygiene Committee of Boston. This organization, at eleven stations in the congested parts of the city, supplies at cost, pure milk, modified when necessary, to meet the requirements in each case.

At each station a graduate nurse instructs the mothers in the care of their children, and medical advice in feeding problems can be obtained. The fact that among the babies cared for in this way last year the mortality was only one-fifth as great as that among babies of similar circumstances not treated proves the practical value of the charity.

The Floating Hospital, the Children's Hospital and the Dispensaries do a great work in saving babies who are actually sick. The final result, whether the infant, weakened by illness, becomes reinfected or not, depends upon its treatment after leaving hospital care. The mothers, as a rule, are more than willing to do all they can, but hampered by large families, by poverty and by ignorance, they are only too likely to become careless. The encouragement and practical help of the milk stations goes far towards remedying this.

We admit to our country annually thousands of families ignorant of the situation which they must face; we supply them with dark, evil-smelling, crowded dwellings and surround them with labor conditions and impossible prices which absolutely prohibit hygienic living.

If we wish to limit their increase, it should be done in some other way than by the death of babies. If, on the other hand, we wish to make them useful rather than detrimental citizens, we must educate them and, when necessary, give them practical aid. For such a service the Milk and Baby Hygiene Committee appeals for help.

EUGENICS AGAIN.

THE transmission to their children of moral, mental and physical defectiveness by people unfit for parenthood is familiar to no one more than to the physician. The baby deficient in vitality, the child lacking in intelligence or in special sense, the youth of perversions and abnormal cravings, come, in one way or another, to his cognizance. Such a law as that passed recently by New Jersey should meet with the careful consideration of the profession. "Every applicant for marriage in the state must have a license secured from an official register. As an essential to that, each person must endure rigid questioning, false answers involving a penalty of from one to three years' imprisonment. No license can be issued to a person under the influence of liquor, or narcotics, to an imbecile, an epileptic, or to one who has been an inmate of an asylum, except as full discharge is in evidence."

Registers, justices of the peace and clergymen are held responsible under heavy penalties for the enforcement of the law.

Every human ill cannot be laid at the door of procreation by the unfit, nor do all those unfit to procreate come within the provisions of this law. It will be interesting, however to see whether preventing marriage between these persons will indeed prevent their having children. It will at least give the law a chance to put such people where they cannot repeat their offense. The passage of the law itself, however, is an indication that the public is at last taking the stand that freedom for the individual, no matter what the cost, is not the liberty for which our forefathers fought. Study of the question is bound to result in public good.

LUNCHES FOR SCHOOL CHILDREN.

WITHIN the past two years, the hygiene department of the Home and School Association has organized in seven of those Boston Schools, which are attended largely by poor children, a "penny lunch" system. Plain, inexpensive, yet nutritious food, such as bread and milk, cereals, and fruits, is prepared by the cooking class and served at 10.30 A.M. to such children as desire

it for a cent apiece. To those householders accustomed to butchers' and grocers' bills of the first magnitude, the idea of getting up any sort of a meal at such a price seems absurd. At Valparaiso University, Indiana, the management for some years has provided breakfast and supper for the student at four cents a meal, and a four-course dinner for ten cents, and according to the man who investigated this system for *McClure's Magazine* of May, 1908, the food was satisfying both in quantity and in quality. Cheap meals, therefore, can be prepared by those who know how, and that the Home and School Association has this information their results indicate. Of a class of forty normal children who were not served with meals, half lost weight, twelve gained and the rest remained the same. Of forty anemic children, given the extra lunch, only eight lost weight and the other thirty-two gained.

The "penny lunch," therefore, especially when combined with the open air classroom, gives to the little unfortunates not only greater vitality and mental snap, but a better resistance against tuberculosis, on account of which the system was originated.

MEDICAL NOTES.

Cholera. — It is announced that several deaths from cholera have occurred among emigrants in Berlin.

Registration in Dentistry. — Ninety-four dentists have passed the State Board of Registration out of one hundred and fifty-one applicants In this number there are apparently no women.

Society for Clinical Serology. — The Society for Clinical Serology was organized at the Mt. Sinai Hospital in New York City on May 9, 1910, when the following officers were elected: David J. Kaleski, M.D., President; Howard Fox, M.D., Vice-President; Walter J. Heimann, M.D., Treasurer; Mortimer Warren, M.D., Secretary, 39 East Twenty-seventh Street. The object of the Society is the cultivation of serological methods as applied to clinical medicine. Meetings will be held on the second Friday in October, December, February and April. The Society is making an effort to effect a standardization of material used in the Wassermann reaction in order to bring about uniformity of results.

Straw Itch. — Straw itch may be considered a new disease, or possibly more properly, a disease of which we have but recently acquired definite knowledge according to the United States *Public Health Report*. In the early part of the summer of 1909, there was an outbreak of an eruptive skin disease among sailors in Philadelphia. The disease was studied by Goldberger and Johanberg who ascertained that the cause was a small mite (pediculoides ventriconus) in the straw of mattresses on which all those affected with the disease had either slept or had put their clothes. Outbreaks of what is in all probability the same disease have been reported from various points in New Jersey, Maryland, Pennsylvania, Ohio and Indiana. The mite preys upon the larvæ of certain insects which live on grain and especially wheat. It remains on the straw and may attack man during the handling of the grain as in thrashing, or if the straw is used in filling mattresses those sleeping on them may be infected. The main symptoms of the disease are a severe itching and an eruption consisting of wheels surrounded by vesicles which develop in a few hours into pustules.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston.— For the week ending at noon, July 5, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diptheria 40, scarlatina 20, typhoid fever 4, measles 86, smallpox 0, tuberculosis 56.

The death-rate of the reported deaths for the week ending July 5, 1910, was 17.88.

Boston Mortality Statistics. —The total number of deaths reported to the Board of Health for the week ending Saturday, noon, July 2, 1910, was 188, against 170 the corresponding week of last year, showing an increase of 18 deaths and making the death-rate for the week 15.56. Of this number 96 were males and 92 were females; 183 were white and 5 colored; 136 were born in the United States, 48 in foreign countries and 4 unknown; 44 were of American parentage, 122 of foreign parentage and 22 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 29 cases and 1 death; scarlatina, 20 cases and 1 death; typhoid fever, 4 cases and 1 death; measles, 129 cases and 2 deaths; tuberculosis, 106 cases and 18 deaths; smallpox, 1 case and 0 deaths. The deaths from pneumonia were 16, whooping cough 0, heart disease 20, bronchitis 1. There were 12 deaths from violent causes. The number of children who died under one year was 47; the number under five years, 66.

The number of persons who died over sixty years of age was 45. The deaths in public institutions were 84.

Cerebrospinal meningitis, 3 cases and 1 death.

Of the above infectious diseases the following were non-residents: Consumption, 8 cases and 1 death. Cerebrospinal meningitis, 2 cases. Scarlet fever, 1 case. Diptheria, 1 death.

Deducting deaths of non-residents, the total is 169 and the death-rate is then 13.99.

DEAN OF YALE MEDICAL SCHOOL. — It is announced that Dr. George E. Blumer, professor of Medicine at the Yale Medical School is to succeed Dr. Herbert G. Smith as dean. Dr. Smith has served in the capacity of dean for twenty-five years.

PRESENTATION TO DR. CHARLES W. PAGE. — At the recent graduating exercises of the training school for nurses of the Danvers State Hospital, Dr. Charles W. Page, the retiring superintendent, was presented a loving cup by the members of the hospital staff.

BOSTON FLOATING HOSPITAL. — The Boston Floating Hospital began its work for the year on July 1. The number of patients on the first day was considerable and there is no doubt that the service of this charity to the community will be equal to that of preceding years.

HONORARY DEGREES. — Dr. John H. McCollom, professor of contagious diseases at the Harvard Medical School and superintendent of the Boston City Hospital, has received the honorary degree of M.Sc. from Dartmouth College.

Dr. Theobald Smith, professor of comparative pathology at the Harvard Medical School was given the degree of D.Sc., at the recent commencement of Harvard University.

At the commencement of Princeton University, on June 14, the honorary degree of LL.D. was conferred upon Dr. William H. Welch, of Johns Hopkins. Dr. Francis Volk, Professor of Ophthalmology in the New York Post-Graduate Medical School, received the degree of Doctor of Science from Washington College at Chestertown, Md., on June 15.

At the commencement of Yale University, on June 22, the honorary degrees of Doctor of Science and Master of Arts were conferred respectively upon Drs. Simon Flexner and William B. Coley, of New York. Dr. Lucien Howe, of Buffalo, was given the degree of Doctor of Science at the commencement of Bowdoin College, on June 23.

BOSTON'S FOURTH OF JULY. — Certainly nature did all in her power to assist Boston in her plan for a "safe and sane" holiday. The program for the day, which included an athletic meet, a regatta, numerous parades and concerts, and, in the evening, fireworks, was well calculated to keep the small boy busy running from one show to another. Aside from the military bands, no one made very much noise, yet every one seemed contented and imbued with more of the true holiday spirit than on previous Fourths. At this writing, the only returns of injuries are those due to the collapse of a float, an accident involving twelve girls, and other injuries, amounting to less than a third of previous years.

NEW YORK.

BEQUESTS. — By the will of the late Mrs. Mary E. Leavitt of New York, $7,000 is left to St. Luke's Hospital, and $3,000 to the Sheltering Arms Orphan Asylum, to establish beds in memory of her mother, Elizabeth Bell Barker.

VETO IN FAVOR OF MEDICAL SOCIETY. — Mayor Gaynor has vetoed the bill passed by the legislature taking away from the Medical Society of the County of New York the revenue received from the fines imposed in cases brought at its instance, to which the society is entitled under the present law.

OPENING OF HOME FOR CONVALESCENT CHILDREN. — On July 1 the Home for Convalescent Children at Chautauqua, Westchester County, the latest addition to the charitable agencies of the Children's Aid Society, was opened. The Society's Coney Island Health Home for women with sick and ailing babies and Bath Beach Summer Home for children had previously been opened for the season.

RED CROSS HOSPITAL NURSES. — The first class of trained nurses, five in number, at the Red Cross Hospital was graduated on June 16. Although the hospital was incorporated in 1902, for some years it occupied very small quarters, and it was not until the present commodious building on Central Park West was erected that it was enabled to maintain a regular training school.

JULY FOURTH. — Notwithstanding the efforts of the authorities in the direction of a "safe and sane" Fourth, the City Health Department did not relax in its precautions to protect the injured from tetanus. A large corps of medical inspectors was on duty throughout the day, prepared to

administer antitoxin to wounded patients, and, in addition, the department supplied the antitoxin free of charge to all physicians. Furthermore, Health Commissioner Lederle issued to the public a warning setting forth the dangers from lockjaw and the efficacy of tetanus antitoxin as a preventive, and stating that the treatment could be secured by simply telephoning to the nearest station of the department. A novel feature of the celebration of the Fourth this year was the singing of several hundred public school children at Bellevue and other hospitals and at the institutions on Blackwell's Island. This was due to the efforts of Mrs. Rice, the founder and organizer of the "Anti-Noise Society" of New York.

A New Fireman's Helmet. — A new helmet, designed to protect firemen from inhaling smoke, gas and ammonia fumes, was recently successfully tested in a smoky fire in the basement of a feather warehouse. A fireman, who was sent into the fire wearing the helmet, reported that, unlike other helmets which had been tried, it had effectually kept out the smoke without interfering with his vision or hampering him by its weight. This new helmet is to be further tested as opportunity is afforded. In general, it resembles a diver's helmet, and is constructed of leather, with a glass front. In the back is a small cylinder containing water, which is made to drop in regulated quantities upon a chemical preparation (sodium peroxide) contained in a compartment below; thereby generating oxygen by a process which, it is stated, is much the same as that employed in the making of acetylene gas. The oxygen is supplied to the mouth of the wearer by means of a tube, which he holds between his teeth. In addition, this ingenious device is equipped with a small bulb horn, like that of an automobile, to be sounded by the fireman as a signal in case of trouble.

Spicula of Bone inside Pleura. — In making an autopsy recently at the morgue on the body of Michael Minnicz, a Russian who had committed suicide by inhaling illuminating gas, Drs. O'Hanlon and Loughan were surprised, on opening the left lung, to find a spicula of bone just inside the pleura. There were no evidences of inflammation or other indications of recent injury in the locality. By the finding of the card of Dr. M. L. Weil in the clothing of the deceased they were enabled to obtain an explanation of this curious discovery. It appears that soon after Minnicz arrived from Russia, three years ago, he was shot and robbed by thugs, who left him for dead. He was not fatally injured, however, and at Mount Sinai Hospital a bullet was found under the skin at the eighth rib on the left side, and removed. From the character of the wound it was evident that the bullet had passed around the left scapula and struck the eighth rib, from which it had chipped off a piece about a quarter of an inch long. Though unsuspected at the time, the latter was driven through the pleura, and it was this spicula which was discovered at the autopsy. It was learned that the man had head trouble after the assault and robbery and seemed to be insane, and that for a long time he had been morose and apparently in pain.

Opening of Junior Sea Breeze. — "Junior Sea Breeze," the summer camp for sick babies on the grounds adjacent to the Rockefeller Institute, has been opened for the fifth season. The site, which is on a bluff overlooking the East River, is provided by Mr. Rockefeller, and the camp is maintained by the New York Association for Improving the Condition of the Poor. There is a competent medical staff and a corps of five trained nurses who, in addition to their duties at the camp, visit regularly in the homes of the poor living in a district extending from Fifty-fifth Street to Seventy-second Street, and from Third Avenue to the East River. They do this work so thoroughly that it has been found possible to withdraw the Health Department nurses from the district named in order to give more attention to other portions of the city not thus provided for. These nurses go to the home of every family in the district in which a birth has been reported, and in the first week of their service they found that out of 195 newborn infants visited, the birth had been attended by physicians in only 34.

Investigation of Private Hospitals. — At a meeting of the State Board of Charities, held June 15, a report was received from a special commission headed by Robert W. Heberd, recently Commissioner of Charities, giving the results of an investigation of some sixty private hospitals in New York City. A number of evils were found to exist, and the board adopted a series of resolutions which the commission recommended in consequence of the discovery of these conditions. These provide, among other things, that no patient shall be maintained at public expense in any ward of any hospital wholly or partly under private control unless the building

is fireproof or its fire protection facilities have been formally approved by the State Board of Charities; unless the building is in good sanitary condition, and unless the wards provide at least 1,200 cubic feet of air space for each bed. In extraordinary instances the air space allowable may be reduced to 800 feet, but only on written permission of the board. At this meeting, applications for certificates of incorporation were granted to the Tuberculosis Preventorium for Children near Lakewood, N. J., and to the new Hempstead Hospital at Hempstead, Long Island.

REPORT OF METROPOLITAN SEWERAGE COMMISSION. — On July 1 the Metropolitan Sewerage Commission presented a report to the mayor, which was similar in character to previous reports by the New York Bay Pollution Commission of which it is the successor. The president of the commission is the well-known sanitary expert, Dr. George A. Soper. Dr. Linsly R. Williams is a member, and the other three members are engineers. The report states that the sewerage being emptied into New York Harbor is a menace to the public health, and recommends the creation of an interstate board by New York and New Jersey for the permanent protection of the harbor. The Commission's investigations included several thousand chemical and bacterial analyses made to determine the digestion capacity of the harbor waters for sewage. Tidal studies, carried on in co-operation with the United States Coast and Geodetric Survey, showed that the drainage which is discharged into the harbor is not flushed out to sea, but is assimilated by the water. If more sewage is emptied into it, than can be disposed of in this way, intolerable conditions will result. Even at present, it is dangerous to bathe in these waters above the Narrows, and the recommendation is made that the public bathing establishments along the docks of Manhattan should be abandoned. Oysters and other shellfish taken from the upper harbor are unfit to eat. To keep all sewage out of the harbor would cost a prohibitive amount. The best that can be done is to remove as much as possible of what is harmful in the sewage and discharge the rest under the most favorable circumstances. Against great trunk sewers, such as have been proposed for the Passaic and Bronx valleys, the commission is unalterably opposed, on account of the immense volumes of sewage which would thus be emptied into the harbor. Such inland communities, the report says, should deal with their sewage in a more modern and sanitary way.

6. RICHTER, G., AND WEINSBERG, C. H. *A Case of Dextrocardia.*

2. Ziegel discusses some of the affections clinically simulating typhoid fever, especially intestinal sapremia, coli infections, meat poisoning, paratyphoid fever and, most important of all, Brill's disease. This last is the name given to a symptom-complex similar to, but distinct from, typhoid fever. The clinical differences between the two diseases are pronounced. The most striking difference is in the eruption which in Brill's disease appears as a single crop, usually before the seventh day. There are no new crops. The rash is profuse and sometimes conglomerate. The spots are maculopapular and usually have an oval, indistinct outline. The eruption fades rapidly at the time of defervescence. The febrile invasion is usually abrupt and is ushered in with a chill or chilly sensations followed by very severe headache and high fever. The temperature curve reaches its height in about three days and remains high until a crisis or rapid lysis brings it down. Apathy and prostration develop very early, and the patient ill with Brill's disease looks as sick in the first week as the typhoid patient in the second or third. In Brill's disease recovery is prompt at the time of defervescence; after the temperature has remained continuously high for a week of two, there is a fall to normal in from ten to sixty hours, and in the great majority of cases the temperature never again rises above normal. No case has been observed with a relapse or with serious sequelæ, and the mortality is nil. The white count is normal, the Widal tests negative and cultures from the blood, urine and feces unproductive.

6. Griscom and Pfahler report results with Röntgen therapy in gynecology. They find that the x-ray can decrease or obliterate the functions of the ovaries and that it can control menorrhagia and metrorrhagia due to myomata; it can also control other menstrual disorders due to overactivity or increased irritability of the nervous mechanism connected with the ovaries. X-ray treatment should be confined at present to inoperable fibromata and menstrual disorders in which other forms of treatment are not advisable.

11. STOKES, A. C. *Injection of Paraffin into the Appendix in an Attempt to Cure Indirect Inguinal Hernia.*
12. *BOGGS, T. R. *Alum Baths in Typhoid Fever.*

1. Fairchild believes that in the chronic forms of suppurative nephritis of hematogenous origin decapsulation is of great value. This will suffice in a great many cases. Others more severe, however, require incision and drainage. The results in either case are generally good.

2. MacLaren shows the efficiency and also the safety of instituting rectal drainage in that type of peritoneal infections, generally following a perforative appendicitis in which, after a few days subsequent to the abdominal operation, the temperature goes up, the patient complains of pain in the pelvis, is doing poorly and rectal examination shows bulging of the anterior rectal walls. His illustrative cases are striking and show that rectal drainage is as efficient as, and not more dangerous than, vaginal drainage. The efficiency of the procedure is shown by the fact that most of his cases were young boys. He advises stretching of the sphincter at the time in order to prevent any possible backing up later.

10. Wheaton believes that he has discovered a new diagnostic sign in early pulmonary tuberculosis. It is observed that when the skin over the area of infiltration is pinched up between the thumb and forefinger it can be drawn away from the chest wall with ease and seems more freely movable than on the mormal side, and if rolled between the fingers it will feel in consistency much thinner than a fold of skin taken from the sound side. He also claims that if there is bilateral involvement the sign can be demonstrated on both sides, but will be more pronounced over the original area of infiltration. The value of the sign is that it occurs early in the process.

12. Boggs has found an alum bath for typhoid patients most efficacious in preventing the occurrence of bed sores, dermititis and skin infections. His prescription is as follows. "One pound of powdered alum is quickly dissolved in a little hot water and added to the tub during the filling. With the average tub of 450 to 500 liters, this makes approximately a 1 to 1,000 solution. The cost is about 4 cents per bath. The patient is bathed in the alum solution just as in ordinary water and experiences no inconvenience from the drug." [E. H. R.]

7. *O'NEIL. R. F. *Necrosis of the Bladder with Exfoliation. A Consideration of the Subject with Two Previous Unreported Cases.*

1. MacCarty's most excellent paper on gastric ulcer is worth careful study. A résumé is as follows. 1. Ulcers may be single or multiple, and in different degrees of extension in the same specimen. 2. After the initial destruction of the mucosa, there is definite deepening of the ulcer by necrosis, which is sufficiently slow to allow a dense, connective tissue barrier against perforation to be formed. 3. Ulcers heal, perforate and become malignant. 4. One cannot say positively that all carcinomata of the stomach have developed on ulcer, because carcinomatous tissue in the base of an ulcer may be an ulcerated primary carcinoma. 5. The length of the clinical history is no positive index of the extent of the lesion. 6. The absence of blood in the vomitus or gastric contents at the time of laboratory analysis when associated with gastric symptoms is not evidence against the presence of ulcer, nor is absence of hyperacidity evidence against the presence of ulcer. 7. Clinically, it is impossible to say that a gastric ulcer is not malignant.

4. Halpenny believes that the thyroid and parathyroids are similar in function, not antagonistic or corrective of one another. In many instances one is able to assume the functions of the other. Though the parathyroids are not rudimentary thyroids, the whole apparatus is essentially one.

7. O'Neil has a very thorough and well illustrated (by cases) article on necrosis of the bladder with exfoliation and appends the histories of all the collected cases. He concludes as follows: 1. Necrosis of the bladder occurs as a result, primarily, of interference with the circulation of the organ aided by bacterial infection. This interference may be produced by mechanical pressure outside the bladder or by bacterial inflammation within the bladder wall. 2. The condition is more common in women than in men. 3. The clinical symptoms are vague. Retention (when associated with cystitis) which cannot be relieved with catheter should excite suspicion. 4. There is a typical cystoscopic appearance by which the diagnosis can be made if the examination is made at a certain time. 5. The prognosis as to life on the whole is good in women. In severe cases permanent injury to the urinary function will result. The prognosis in men is good if the membrane is removed. 6. Operative treatment is always indicated in men, occasionally in women. 7. The lesion is a rare one. [E. H. R.]

THE LANCET.

9. HIRSCH, C. T. W. *Motoring Notes.*

2. In a discussion on the relation of fibrosis to tuberculosis of the lung, Williams first describes three forms of fibrosis, one arising from pleural inflammations, one accompanying or resulting from interstitial pneumonia, or the result of such chronic changes following inhalation of iron filings, stove dust, etc., and the third form supervening on tuberculosis. He briefly describes the pathological features of this condition and then discusses the clinical aspect, especially where the fibrosis is the result of tuberculosis. As this condition comes on, all the patient's symptoms improve except the shortness of breath; there is apt to be a marked shrinkage of the affected lung. He

presents the details of several cases. He defines fibrosis as the process by which nature resists the advance of tuberculosis and limits its inroads.

3. Poynton and Paine review and bring up to date the work done on the etiology of rheumatic fever and allied conditions with especial reference to their own careful investigations. They conclude that no explanation of acute rheumatism can compare with that which attributes it to an infection with a diplococcus of the streptococcal group.

6. Williams in an examination of 3,159 children finds that 16.2% show signs of pulmonary tuberculosis. She urges physicians to begin treatment and to realize the gravity of the condition before local signs in the lungs are marked. Her paper is largely a defense of her own previous work against certain criticisms brought against it. She presents statistics from Naegeli, Hamburger and Sluka and others, and discusses them. [J. B. H.]

7. STRETTON, J. L. *A Further Contribution on the Sterilization of the Skin of Operation Areas.*

2. Gordon emphasizes the fact that the percussion outline of the heart is markedly altered on change of position and that in cardiac disease this is still more marked. He believes that this point receives far too little attention. He illustrates by diagrams the changes to which he refers. In the erect position the actual position of the heart as shown by the x-ray practically corresponds with its position as determined by percussion; in the recumbent position, however, while by percussion the left border is still fairly accurate, the right border rarely goes beyond the mid sternum and is very far from corresponding with the heart's rightward limits. This is still more striking in cardiac disease. Therefore, according to the writer, the value of transverse cardiac measurements, unless it is stated in what position they are taken, erect or recumbent, is absolutely nil.

6. Clarke and Forsyth discuss their work on the differential cutaneous reaction in tuberculous diseases as originated by Detri. Their work is illustrated by various tables. They conclude that: (1) Any patient giving either or both reactions is certainly tuberculous, but the reaction gives no indication of the site or activity of the lesion (2) Any patient giving no reaction is certainly not tuberculous except in certain advanced or moribund cases. (3) Both reactions are usually present in pulmonary tuberculosis. It is accordingly better to treat patients with both human and bovine tuberculin.

4. Hoffmann, in a short note, mentions the fact of the successful inoculation of guinea pigs with the spirochete of syphilis. He considers that this form of inoculation will be of considerable value in experimental work along these lines.

5. Reviewing briefly the work of different authors in their methods of infecting rabbits with syphilis on the scrotum or testicle, Tomasczewski presents a new method of his own of implanting a bit of suspected material in a rabbit's testicle forced out through inguinal ring. In from ten to eighteen days later spirochete may be obtained from the sore and also they can be demonstrated in the tissues. In this way he feels that he has an easy and quite rapid way of making a diagnosis, before waiting for later symptoms to develop in the individual or animal. [C. F., JR.]

2. Brückner shows with large figures that typhoid occurs more often in children under fifteen years than at any subsequent age. He draws the following conclusions: That the age between eleven and fifteen is the most susceptible period; that typhoid in children often runs such a mild course as to be ignored and that such cases may be an important source of epidemics; that to prevent the spread of typhoid careful watch of the schoolchildren is essential; and that the practitioner should make more use of the laboratory, especially in cases of fever when a definite diagnosis is lacking.

3. Experiments of the writer show that the rising of the diaphragm, sometimes observed with inspiration in pneumothorax, is due to mechanical causes and that when these are removed the diaphragm works in the usual way. This paradoxical movement is due to negative pressure in the affected side of the chest and to a lung which fails to expand. By admitting air freely through a fistula the negative pressure is removed and the paradoxical diaphragm phenomenon disappears.

11. The complement-binding reaction tried in 30 cases of typhoid did not occur in 7 of these. The writer says that the blood culture is the best means for early diagnosis, that next to this comes the white count, the agglutination test follows in percentage of value and the complement-binding test follows that. Leucopenia (i. e. counts below 7,000) appears in the first week, increases later and is present in a high percentage of cases. The results in this respect correspond with those of other writers. Lüdke reports also on the use of a serum of his own. No harm followed its use, but although the writer believes it did good beneficial results were not striking. [G. C. S.]

13. By listening with a stethoscope to an artery compressed above by a band, different tones and different volumes of sound will be audible depending upon the amount of constriction; these may usually be divided into three successive classes as pressure is reduced on the artery. Variations from the normal in the occurrence of these auscultatory phenomena were obtained by the author mechanically, by the use of drugs and in disease. He feels that in this method we have another means of testing the physiological efficiency of the heart.

16. Shirokauer and Wilenko examined the blood and organs of rabbits for diastatic ferment after producing glycosuria by administration of adrenalins. Finding no increase in amount of ferment, they are led to believe that the rapid formation of sugar in this condition is due to increased activity of the normal liver diastase.

19. Of the two influences on the heart, Pawinski considers the nervous as important as that of organic disease. He speaks first of the effect of heart disease upon the patient's spirits and finds two general classes of mental effect, the one an excitation and happy disposition seen particularly in young people with aortic insufficiency, the other bad temper and hypochondriasis associated with mitral disease.

He then classifies five forms of neurotic heart conditions which may be readily mistaken for organic.

(1) Takes the form of a sudden dyspnea coming on especially during rest. Symptoms may disappear for weeks to recur with some nervous excitation.
(2) Simulating asthma, in women at the climacteric.
(3) Hyposthenia cardio-vasculosa climacterica.
(4) A pseudo-angina occurring in men.
(5) Pseudo-angina of young nervous women.

Sclerophasia is to be counteracted in every way.

From the point of view of diagnosis, prognosis and treatment the author feels that these forms of cardiac neurosis should be recognised more generally. [J. B. A.]

REVUE DE CHIRURGIE.

MAY, 1910.

7. CHEVASSU, M. *The Surgical Treatment of Cancers of the Testicle.* (Conclusion.)
8. KÜSS, G. *Pelvic Pericolic Strictures, Principally in the Female.* (To be continued.)

3. The occurrence of a death, the second on record, during the use of Momburg's method of artificial anemia of the lower half of the body is reported by Gross and Binet. The patient in considerable cachexia from prolonged, suppurative tuberculous arthritis of the knee, but without demonstrable cardiac lesion, died from sudden cardiac standstill at the moment of removal of the waist tourniquet, after disarticulation of the hip-joint. The authors believe the death due to sudden change in blood-pressure, and report the case as indicating the need of great caution in the use of this method. [It may be suggested that the death may have been due in part to chloroform and might not have occurred had ether been employed instead as an anesthetic.]

4. From the study of paralyses due to injuries to the roots of the brachial plexus, the writer concludes that there are such paralyses of a complex type, differing sensibly from the classic types of brachial paralysis, with predominant motor phenomena, liable to confusion on account of being masked by associated symptoms of disability due to concomitant trauma of other tissues and structures. The ultimate prognosis of this group of lesions he considers fairly good, at least functionally. Treatment may be by primary suture of the injured nerve trunks or by secondary orthopedic repair of the peripheral deformities consequent to the paralysis. [R. M. G.]

Correspondence.

THE QUESTION OF SERUM THERAPY.

BOSTON, June 28, 1910.

Mr. Editor, — There seems to be so much zeal shown at the present time for "Serum Therapy" and the strict scientific method in medicine, that I wonder if the average enthusiast in those lines gets a very practical perspective of some of their untoward effects. The man who is so dependent upon his microscope and test tube becomes, as it were, immune to seeing the bugs which are developed in the mental and spiritual mediums. The little entities are very interesting as studied in laboratory hot houses but there is a large world outside of entirely different perspective and dimension, and this is peopled with devils of a very different character.

A year ago I attempted to discuss some "Principles of Therapeutics by Sense Culture" in this JOURNAL. I have been led to see more and more the subtle effect of such influences, light, color, dimensions; odors have a power in influencing our state of mind and the effect of music is familiar to all.

"Baths" promote good feeling and "taste" should always be up for consideration.

The devotion to laboratories and hospitals may harden a physician to a clear understanding of the finer humanities, methods which, though justified by some ultimate results, may be adding to the flames that drive patients to schools of thought and practice which the regular practitioner cannot countenance.

The true physician is to become more and more a sanitary engineer and counsellor. He must collaborate with the architect and minister. He must be trained to foresee and avert what affects the finer human sensibilities. By such fineness of instinct and training he will regain confidence which he once held — he will return to his own fold those who have been wandering in other pastures.

Very truly yours,
P. W. GOLDSBURY, M.D.

LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND OTHER OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED JUNE 22, 1910.

GLENNAN, A. H., assistant surgeon-general. Granted one month's leave of absence from July 11, 1910.

COFER, L. E., assistant surgeon-general. Granted four days' leave of absence from June 22, 1910.

WERTENBAKER, C. P., surgeon. Granted four days' leave of absence from June 27, 1910.

WILLE, C. W., passed assistant surgeon. Detailed to attend the joint meeting of the Ohio State Board of Health with local boards of health, to be held in Cleveland, Ohio, June 30–July 1, 1910. June 15, 1910.

LONG, J. D., passed assistant surgeon. Relieved from duty in the Hygienic Laboratory and detailed for duty in the Bureau as Assistant Surgeon-General in charge of the Division of Domestic (Interstate) Quarantine, effective June 16, 1910. Paragraph 12, Service Regulations.

STIMSON, A. M., passed assistant surgeon. Granted four days' leave of absence from June 15, 1910, under paragraph 191 Service Regulations.

ROBERTS, NORMAN, passed assistant surgeon. Granted one day's leave of absence June 13, 1910, under paragraph 191, Service Regulations.

FROST, W. H., passed assistant surgeon. Granted two days' leave of absence en route to station.

MULLAN, E. H., passed assistant surgeon. Granted thirteen days' leave of absence from June 17, 1910.

STILES, C. W., professor, chief, division of zoölogy, Hygienic Laboratory. Detailed to attend the annual meeting of the Medical Society of North Carolina, to be held at Wrightsville Beach, June 23, 1910. June 16, 1910.

DELGADO, J. M., acting assistant surgeon. Granted twenty-six days' leave of absence from July 1, 1910.

HOUGH, J. SPENCER, acting assistant surgeon. Granted thirty days' leave of absence during the calendar year 1910.

HUNTER, W. R., acting assistant surgeon. Granted ten days' leave of absence from June 18, 1910.

O'NEILL, A. A., acting assistant surgeon. Granted three days' leave of absence without pay, from June 10, 1910, under paragraph 210, Service Regulations.

RICHARDSON, S. W., pharmacist. Relieved from duty at the Pensacola Quarantine Station, and directed to proceed to Boston, Mass., and report to the medical officer in command for duty and assignment to quarters. June 14, 1910.

ILTIS, G. W., pharmacist. Relieved from duty at Boston, Mass., and directed to proceed to Pittsburg, Pa., and report to the medical officer in charge for duty. June 17, 1910.

APPOINTMENTS.

ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH. — The Board of Directors of the Rockefeller Institute for Medical Research announce the following promotions and appointments for the year 1910–1911. Laboratory Staff: Member, Jacques Loeb, experimental biology. Associates; W. A. Jacobs, biological chemistry; D. R. Joseph, physiology and pharmacology; Peyton Rous, pathology; B. T. Terry, protozoölogy; D. D. Van Slyke, biological chemistry. Assistants: M. T. Burrows, experimental surgery; P. F. Clark, bacteriology; I. S. Kleiner, physiology and pharmacology; Hardolph Wasteneys, experimental biology. Fellows: F. J. Birchard, biological chemistry; F. B. La Forge, biological chemistry. Scholar: J. Bronfenbrenner, pathology. Hospital Staff: Resident physician, G. Canby Robinson. Internes: George Draper, H. K. Marks, F. W. Peabody, H. F. Swift. General manager: Jerome D. Greene.

SOCIETY NOTICE.

AMERICAN HOSPITAL ASSOCIATION. — The twelfth annual conference of the American Hospital Association will be held at the Planters Hotel, St. Louis, Mo., Sept. 20, 21, 22 and 23, 1910.

RECENT DEATH.

DR. CHARLES ZELLHOEFFER, of Brooklyn, N. Y., died on June 29, at the age of fifty-nine years. He was graduated from the medical department of the University of the City of New York, in 1873, and at the time of his death was consulting to the German and the Eastern District Hospitals, Brooklyn.

THE OCCURRENCE OF INFANTILE PARALYSIS IN MASSACHUSETTS IN 1909.*

REPORTED FOR THE MASSACHUSETTS STATE BOARD OF HEALTH, BY ROBERT W. LOVETT, M.D., BOSTON.

THE medical profession of to-day is confronted with the task of constructing a new literature on the subject of infantile paralysis. What was written five years ago is to-day largely out of date and the standard textbooks cannot naturally present the latest point of view, so rapid has been the recent progress of our knowledge in regard to this disease. The chief contributors to this rapid advance have been, first and foremost, Flexner and Lewis in demonstrating the etiology, Wickman, of Sweden, in giving us a new symptomatology and defining types not before recognized, and Harbitz and Scheele, of Norway in formulating the pathology.

The present paper will consist, first, of a condensed report of the recent progress of our knowledge with regard to the disease, and, secondly, of the data obtained with regard to the disease in this state in 1909 by the State Board of Health.

I. REPORT OF PROGRESS.

The most important step in our knowledge of the disease consists in the establishment during the past year of its infectious character by several observers. With the ability to produce the disease in monkeys by inoculation, there has been given the opportunity to study its etiology, symptoms and pathology, which opportunity did not exist before.

EXPERIMENTAL PRODUCTION.

Infantile paralysis has been recently shown to be an infectious disease caused by a living organism so small that it can pass through the finest bacterial filter. It is invisible to the microscope and the ultramicroscope.[17] This places the disease in a class with those caused by a filterable virus, similar diseases of this class being yellow fever, foot and mouth disease, pleuropneumonia of cattle, etc. It can be caused in monkeys by inoculation with an emulsion of certain tissues from a human being dying of the disease, and from affected monkeys.[41, 17, 10, 30, 50]

The virus is contained in the brain and spinal cord, the mucous membrane of the nasopharynx, infected lymphatic glands, in the salivary glands,[10] and in the acute stage in the blood and cerebrospinal fluid.[17]

The disease may be caused by inoculation by the following routes: intracerebral, subdural, intra- and peri-neural, intraperitoneal, subcutaneous, by the circulation, and by implantation in the anterior chamber of the eye.[10, 17, 41]

By the digestive route it has been caused by introducing an emulsion into the stomach by means of a catheter and by introduction of the virus into intestines paralyzed by opium.[41]

By the respiratory route the disease has been caused by rubbing the nasal mucous membrane after scarification[17] with a virulent suspension, by the same procedure without scarification, by inhalation of a virulent emulsion, and by implantation of infected tissue in the trachea.[41]

The fact that the disease may be caused by virus entering both respiratory and digestive tracts must be remembered when we come to inquire how the virus enters the human body.

Inoculations into horses, calves, goats, pigs, sheep, rats, cats, mice,[30] rabbits,[39] chickens,[42] guinea pigs[30] and dogs, have proved negative except for the results of Krause and Meinicke,[24] who caused paralysis in rabbits by inoculation with virulent material, but their results are not generally accepted by other observers as they are in contradiction to practically all other experimental work and not sufficiently supported by pathological evidence.

The virulence of an emulsion is not impaired by drying for seven days, by freezing nor by suspension in glycerine,[10, 17, 30] but is injured by a temperature of 45° to 50° C.[17] The virus is not always affected by dilution, a solution of one to a thousand working as quickly and effectually as the full strength.[41]

The stage of incubation in monkeys is from six to upwards of thirty days, and the long incubation period in monkeys suggests the possibility that in the human being some of the late fall and early winter cases may have acquired their infection when the disease was prevalent in August and September. The ordinary incubation period in human beings is not known. It is generally stated as from one to fourteen days.

IMMUNITY.

One attack of the disease apparently confers immunity to future attacks.[17, 10, 31, 41] This is the accepted clinical history in human beings, and has been found to be the case in monkeys inoculated experimentally.

Active immunization in monkeys has been secured by the repeated injection of small doses of virus repeated many times, after which a full dose has had no effect.[17]

Passive serum protection has been obtained by mixing with an active dose of the virus an equal amount of the blood serum of a recovered monkey, which neutralizes the effect of the virus, and in the same way the blood serum of children who have recovered, when mixed with the virus in proper proportions neutralizes its effect.[17] Attempts to secure a neutralizing serum from horses who have received repeated injections of virus have not been successful. Even if we had at hand a therapeutic serum for this disease, it must be evident that such a serum to be of use must be used early in the disease, and at present our diagnostic knowledge is not sufficient to enable us to use it before the destruction occurs in the cord. The diagnosis is now rarely made

* Portions of this report were read in abstract before a joint session of the American Orthopedic and Pediatric Societies in Washington on May 4, 1910, and before The Massachusetts Medical Society in Boston, June 8, 1910.

before the paralysis occurs, and a better knowledge of the early symptoms and diagnostic signs of the disease is one of our most urgent needs and indicates the line in which our investigation for the present year should progress.

DIAGNOSIS.

In the matter of clinical diagnosis, the last year has added a little to our knowledge, chiefly in the way of a better knowledge of early symptoms. The eight types of the disease as described by Wickman are not, however, sufficiently known in the English language, and a translation of his book would be of great value (Wickman: Beiträge zur Kenntniss der Heine Medinschen Krankheit, Berlin, 1907), although a short abstract has been made of it.[18]

Müller,[22] investigating at the request of the authorities an epidemic in Westphalia in 1909, considered three symptoms of great importance in the early stages. These were (1) tendency to profuse sweating; (2) hyperesthesia and sensitiveness to movements, and (3) leucopenia. Respiratory and digestive symptoms were common in the earlier stages, and the incubation period was at least five days.

Krause,[23] was commissioned by the government in 1909 to investigate an epidemic, consisting of 436 cases, occurring in Germany in the neighborhood of Hagen. He found digestive symptoms present in 90% of all cases at the onset, and occasionally respiratory symptoms. He calls especial attention to the importance of sweating and tenderness as early symptoms.

The later laboratory findings suggest that certain characteristics of the blood and cerebrospinal fluid in the stage preceding paralysis may enable us to make an earlier and surer diagnosis, but these findings have not yet appeared in print.

INCREASING FREQUENCY OF OCCURRENCE.

It is generally believed that infantile paralysis is becoming more common and more widespread of late years, but one must bear in mind that there is a possibility that this is because the disease is better known and more frequently recognized. As this is a matter of importance, it seems proper to examine the evidence on this point.

The recognition of outbreaks of infantile paralysis is of comparatively recent date. Bergenholz, a Swede, writing in 1881, is generally credited with having been the first to recognize and describe such an outbreak with sufficient accuracy to make it acceptable. Since that time, outbreaks have been reported with increasing frequency. From the time of the first generally accepted outbreak until the close of 1909 is roughly thirty years. If this interval be sub-divided into periods of five years, beginning with 1880–1884 inclusive, and ending with 1905–1909 inclusive, and if we set down in each period the number of outbreaks reported, we have the following table:

	Cases.	Outbreaks.	Average Number of Cases.
1880–1884	23	2	11.5
1885–1889	93	7	13
1890–1894	151	4	38
1895–1899	345	23	15
1900–1904	349	9	39
1905–1909	8,054	25	322

DISTRIBUTION OF OUTBREAKS.

The recent outbreaks have been widely distributed. From Norway and Sweden have been reported large and carefully studied epidemics, especially in the last ten years. Zappert,[46] in 1908 and 1909, collected 266 cases in Vienna and lower Austria, and Ghon noted many cases in upper Austria (Styria and Carinthia). In Germany, in 1909, the disease was very prevalent. The Westphalia epidemic of 436 cases [23] has been spoken of above. In Rhenish Prussia there were said to have been about 100 cases, and around Marburg about 50. There were cases in the province of Hanover and about 50 cases in Silesia. Numerous small epidemics were reported. It is estimated that there must have been over 1,000 cases in Germany in 1909.[47] In Holland, 24 cases were reported from Leyden, and others between August and October in other parts of the country.[47]

England seems to have been comparatively immune, and only a small epidemic of 8 cases was reported from Spain. Although no large epidemic occurred in France, there was a consensus of opinion among the medical men quoted by Netter that an unusually large number of cases of infantile paralysis had been seen in 1909.[47], [49]

The United States suffered severely. Minnesota [48] had several hundred cases; Nebraska,[36] 619; Kansas, about 80; and Massachusetts, nearly 1,000.

The report [51] of the New York epidemic of 1907 has just become available for study. The fact that this epidemic of 2,500 cases was the largest ever reported, the painstaking character of the work done and the scientific standing of the committee in charge of the investigation make the report of the greatest importance and value. It is impossible in this place to abstract so condensed and exhaustive a work.

A most interesting and important epidemic of 140 cases has been reported as occurring in 1909 in the Province of Santa Clara, in Cuba.[53] Previous epidemics have been reported from the temperate zones of the north and south hemispheres, chiefly in the northern parts of the former. The Cuban epidemic, as the first reported from the tropics, possesses peculiar interest as to season, distribution, etc. Apparently the disease did not exist in Cuba prior to 1907. In 1907 and 1908 one or two suspicious or authenticated cases appeared in the neighborhood of Havana, the disease becoming epidemic in the Province of Santa Clara in 1909. A survey of the field makes it seem very probable that the disease was imported from New York as a result of the 1907 epidemic there, and that certain unknown determining conditions made the Province of Santa Clara suscep-

tible to a severe outbreak. As in the temperate zones, the disease occurred during the summer, reaching its maximum in July and August. The chief incidence was between the ages of one and three; males were predominantly affected; and the black race was evidently much less affected than the white, in 72 cases the proportion being: Whites, 60; mixed race, 4; negroes, 8. The mortality rate was 7.89%.

The time has gone by when the routine reports of epidemics is of any especial value, nor is the exact tabulation of numbers of epidemics of any particular use except as throwing light on the general distribution of the disease, and possibly in this way defining some of its characteristics.

The disease is manifestly prevalent, and it is widespread and increasing. Useful work in the future will consist in the exact and careful house-to-house study of epidemics both large and small.

Of the 8,054 cases reported in the last five years (a number, of course, only approximately correct), the United States contributed 5,514 cases or about five sevenths of the total number of cases. The bulk of these cases has, moreover, been reported from the Northern states, the outbreaks in the Southern states being insignificant. In the same way in Europe, Norway and Sweden contributed about 1,500 cases and Germany practically the rest, except for an outbreak in Australia, which occurred in March, which is their early fall.

As the literature has been very carefully gone over, and as, in the present state of interest in the subject, it seems fair to assume that large outbreaks in any civilized country have been reported, it would seem that the following conclusions were justified:

1. That outbreaks of infantile paralysis have very greatly increased in several parts of the world in the last five years in a measure not to be explained in any way by the increased interest in the disease.

2. That it is more prevalent in cold than in warm countries.

3. That from the northern part of the United States have been reported more cases than from any part of the world.

The study of these 70 outbreaks, reaching over a period of thirty years, has led, of course, to the knowledge of certain facts with regard to the disease, but they have not given us the essential facts as to how the disease enters the body nor how to prevent or check its spread.

RELATION TO INFLUENZA.

A recent book [42] deals with the theory that the disease is merely a form of influenza, a contention already discussed prior to 1905 and antagonized by Wickman. The book in question deals with a study of 303 cases occurring in Sweden, each case being considered by itself. The point of view of the author is shown in the following quotation, "I must, therefore, regard this (the intermittent type of influenza) as a very certain proof for my view, acquired on other grounds, that acute infantile paralysis is a nervous form of influenza." Recent progress in the epidemiology of infantile paralysis makes this view seem improbable.

TRANSMISSIBILITY.

In the writings of the last year there is no dissent from the opinion that the disease is communicable. Direct transmission is apparently frequent, transmission by means of a healthy carrier is more than probable, and infection occasionally appears to remain in a house where the disease had previously occurred.

On the other hand, the disease is evidently not very "contagious" in the ordinary acceptance of the term. In the epidemic in the Deerfield valley, in Massachusetts, in 1908, so carefully studied by Emerson,[2] there were 67 cases. There were 166 other children in the families of those affected, and 86 other children known to be in intimate contact with the 67. Of the 252, 4 later developed the disease.

Hill,[48] of the State Board of Health of Minnesota, has contributed a careful study of the transmissibility of the disease, written in a spirit of scientific skepticism. Of 161 cases reported as anterior poliomyelitis, he accepted only 85 as surely valid, and analyzed 81 of these occurring in 69 families. Sixty-nine of these cases were primary and 12 occurred secondarily in the same families. The secondary cases thus were 17% of the primary. Contrasting this with the records of other infectious diseases in the same state, the percentage of secondary cases to primary was as follows:

	Per cent.
Scarlet fever,	40
Typhoid fever, about,	30
Diphtheria,	29
Anterior poliomyelitis,	17

Of persons known to have been exposed to diphtheria, scarlet fever and anterior poliomyelitis, the percentage contracting the disease was as follows:

	Per cent.
Scarlet fever,	22
Diphtheria,	17
Anterior poliomyelitis,	6

The disease is thus apparently less readily transmissible than the diseases mentioned in persons exposed, but such figures cannot be considered representative until the abortive cases are included.

The study of the epidemiology of a disease falls into two parts, — the study in the laboratory and the study in the field. The most notable contribution as yet to our knowledge of this disease is from the laboratory, where Flexner and Lewis have established its infectious nature. This fact has narrowed the field of our inquiry and enables us to pursue a more definite and promising scheme, but one should remember that work in the field, comparatively fruitless as it has so far been, holds its place. We knew for many years the organism of malaria and the pathological changes occurring

in the disease, but we could not control malaria until we found that it entered the body through the agency of the mosquito. So it is quite possible to us to know much of the bacteriology and pathology of a disease from the laboratory without being able to control or suppress it, and such knowledge must be supplemented by field work; that is, a study of external conditions to round out our investigation and to make it as effective as we should wish.

II. INFANTILE PARALYSIS IN MASSACHUSETTS IN 1909.

In the year 1909, Massachusetts suffered as much from the disease as any country in Europe; as many cases were reported here as in the two other most severely affected states in the Union — Nebraska and Minnesota — taken together.

In Massachusetts, in 1907, we had begun the investigation of the disease by sending out inquiry blanks to be filled in by the general practitioner. That resulted in a loose collection of 234 cases, the results of which were published.[1] In 1908, half of our 136 cases occurring in the state were located in Franklin County, and these 67 cases were thoroughly studied by Emerson, who lived in the district a month for the purpose. These studies were published.[2]

In 1909 it was decided to take up the matter more seriously. A special agent, Mr. Sheppard, a fourth-year student at the Harvard Medical School, was detailed as a special investigator, and in February, 1910, another special investigator was added to the staff in the person of Dr. Hennelly, a recent graduate of the Harvard Medical School and of the Boston City Hospital. It was thought desirable to have expert advice in conducting the inquiry, and three gentlemen were requested to act as an advisory committee to the board. These were Dr. Theobald Smith, Professor of Comparative Pathology; Dr. M. J. Rosenau, Professor of Preventive Medicine and Hygiene, and Dr. J. H. Wright, Pathologist to the Massachusetts General Hospital and Assistant Professor of Pathology, all of the Harvard Medical School. The secretary of the board, Dr. Mark W. Richardson, has given freely of his time and effort in conducting the details of the inquiry. This advisory committee has met the members of the board who are concerned in the inquiry at frequent conferences, studied the reports submitted and advised as to the most promising lines of investigation.

The two investigators have conducted a house-to-house investigation and have filled out their own blanks; they have been instructed to work in all cases through the family physician; they have obtained from the family a careful history of the attack and they have examined the affected children. It has not been possible under these conditions to make rapid progress, and at this time only 150 cases have been thus carefully studied. It seemed to us better to confine the investigation to certain localities, making it exhaustive in certain affected districts in the neighborhood of Boston, rather than to take up a scattered investigation throughout the state. Up to this time the expense of the inquiry had been borne by the board out of its regular appropriation, but in January, 1910, the board asked the legislature for a special appropriation of $5,000 to enable the board to make a proper and adequate inquiry into this disease as it occurred in the state in 1910. This sum of money was voted without question or opposition. It is our purpose to have on hand a sufficient number of investigators during the coming summer to be able to look into the surroundings of every case within forty-eight hours of the time when the case is reported.

In presenting for the board some of the results obtained in 1909, it is only proper to say that in the present state of our knowledge no one can say which data are relevant and important and which are not. It is possible that certain facts which now seem of no importance may be of assistance to some future investigator. So far as practicable, our data are presented in graphic form. There are three classes of cases dealt with in this report: (*a*) The total number reported (923); (*b*) the number in which blanks were filled out (628); (*c*) the number thoroughly studied (150). All three classes are utilized in different tables, some being available for one purpose and some for another.

DISTRIBUTION IN THE STATE.

A consideration of the distribution of the disease in the state of Massachusetts for the past three years shows that in all three years the disease occurred in scattered foci in all parts of the state, but was more frequent in the river valleys than away from rivers; that a case rarely occurred in a town without one or more cases in contiguous towns, and that localities severely affected one year were lightly affected the next, e. g., the outbreak in the upper Connecticut Valley in 1908 was followed by very few cases in 1909 in that region. In the next year but one, however, localities markedly affected may again show many cases, e. g., in 1907 the extreme western end of the state showed many cases, in 1908 almost none, and in 1909 again many cases. The Metropolitan District shows, of course, a large number of cases, and it will be noted that in general there were more cases of the disease in the towns north of Boston than in towns south of it.

DISTRIBUTION IN BOSTON.

Analyzing the relative prevalence of the disease in the different parts of Boston, the distribution of the cases shows nothing. The incidence was greatest in Dorchester, which is on the shore and not altogether thickly settled; next in Charlestown, on the shore and densely populated; next in the city proper, densely settled, and so on, districts on the shore and inland alternating, and density of population having apparently no influence.

RELATIVE DISTRIBUTION IN CITIES AND TOWNS.

There are 354 cities and towns in Massachusetts, in 136 of which there occurred cases of infantile paralysis in 1909. These 136 cities and towns were listed according to the prevalence of the disease in each per 1,000 of the inhabitants. The incidence ran from 526 per 100,000 inhabitants to 15 in 100,000. Taking the first 25 where the incidence per 1,000 was highest, the average population was 3,295, and only 4 towns were over 7,000. Taking the last 25 on the list where the incidence per 1,000 was least, the average population was 34,860, and no city or town was under 7,000 in population. Therefore in 1909 the disease was relatively much more prevalent in small towns than in the cities and larger towns.

GENERAL CONDITIONS.

Aside from the immediate environment of the patients, there are certain general considerations of possible interest.

Rainfall by Years.

The last six years have been very dry. In 1907 there was practically a normal rainfall, and 234 cases in the state. In 1908, a very dry year with 7 inches deficiency of rainfall, there were few cases — 136. In 1909, with more rain (3 inches deficiency) there were 923 cases. In Massachusetts the prevalence of the disease by the year has not, therefore, been coincident with deficiency of rainfall.

DEFICIENCY RAINFALL, 1904–1909, INCLUSIVE.

Year.	Cases in state.	Actual.	Normal.	Deficiency.
1904	...	43.81	45.16	—1.35
1905	...	37.60		—7.56
1906	...	43.21		—1.95
1907	234	44.49		—0.67
1908	136	37.61		—7.55
1909	923	42.10		—3.06
				—22.14

Rainfall by Months in 1909.

The chart of the rainfall in 1909 in the state, arranged by months, does not correspond with the prevalence of the disease in the state arranged also by months, the driest month preceding the month of greatest frequency of the disease in the same way that the driest year preceded the year when the disease was most prevalent.

Temperature by Months in 1909.

The curve of the average monthly temperature in Massachusetts in 1909 does not correspond with the curve of the frequency of the disease, the highest average temperature falling away before the highest incidence of the disease occurs.

NUMBER OF FAMILIES AFFECTED AND POSSIBLE ABORTIVE CASES.

To make the following analyses clearer, the following table is important as showing that the 150 cases carefully studied occurred in 142 families, and also showing the probable existence of a fairly large number of abortive cases associated with them.

The 150 cases of paralysis carefully studied occurred in 142 families. The total number of children under fifteen in these 142 families was 479.

FIG. 5.

The total number of children sick from any cause in these families contemporaneously with the occurrence of paralysis was 187, and 12 adults. Of the 187 sick children, 149 were paralyzed; of the 12 adults, 1 was paralyzed. This leaves 49 cases of contemporaneous illness not followed by paralysis which are to be reckoned as possible abortive cases of the disease.

SURROUNDINGS OF PATIENTS.

The following tables relate to the environment of the patients in the 150 cases carefully studied, and are largely self-explanatory.

The nearness of the house to the railroad was investigated on account of the data of certain Swedish observers, showing its frequency in these localities. Even in a district where railroads were frequent, the bulk of the cases were well removed from the tracks.

Analyzing the age of infected houses, it is evident from the following table that most of the 150 cases occurred in old houses. Yet the majority of houses in a city are old. But in Dorchester, where many cases were investigated, building is active and many of the houses are new. It seemed as if the average age of infected houses was probably higher than that of the houses of those districts taken as a whole.

Prevalence of Vermin, Insects and Rodents.

Inasmuch as the disease in many respects suggests that it is insect-borne, the following table was compiled from the account of the family aided by the observation of the investigators. It may be added that the investigators were fully aware of the importance of obtaining accurate answers to this question.

Among 142 families, 134 had vermin, etc., as follows:

	Families.

Paralysis in Domestic Animals.

The occurrence of paralysis among domestic animals and fowls has been found to coincide with outbreaks of the disease in the human beings in some instances reported. Inquiries were, therefore, addressed to every veterinary surgeon and every animal inspector in Massachusetts as to the occurrence of such paralysis in animals in 1909. The reported cases were then carefully laid off on a map of the state and the relative distribution of the animal cases compared with that of the human cases. No correspondence was found to exist, so that, so far as these data can be depended on, no obvious connection on the whole existed between the two classes of cases in Massachusetts in 1909.

The health of the domestic animals in the 142 families is shown in the table. In 34 out of 87 families having domestic animals, sickness, paralysis or death occurred in these animals about the time of the paralysis in human beings.

The relation of this disease to paralysis in domestic animals is, however, a matter requiring much more extensive investigation and is at present wholly unknown.

RELATION TO RABIES.

The relation of the disease to rabies was investigated and in three of the towns carefully studied epidemics had occurred in the past, but no outbreak of rabies in 1909 had any relation to these 150 cases of paralysis, and no one of the 150 paralyzed children had in the past received the Pasteur treatment.

COMMUNICABILITY.

With regard to evidences of communicability in our series of cases, it seems proper that in so important a matter our conclusions should only be presented after a very careful study of all the facts.

We have had instances of direct contagion from child to child with an incubation period of one to fourteen days. We have had a number of instances of what appeared to be indirect contagion by a healthy carrier, and finally we have had 11 instances in the 150 cases where the

* The following letter which reached the board through the State Board of Health of Minnesota is of possible interest in this connection.

" In my veterinary practice during the past five or six years, I have found a disease appearing among one- and two-year-old colts that show a line of symptoms corresponding very closely to *anterior poliomyelitis* of children. I have had from five to ten cases a year during this time, the cases always occurring during the summer months and the majority of them during the month of August. The affected colts are usually found in the pasture, unable to stand. The owner sometimes will notice an unsteady gait for twenty-four hours before entire loss of motion occurs. At first, these colts have a rise of temperature ranging from 103° to 104° F.; pulse and respiration accelerated; animal sweats profusely; appetite remains fairly good, but there is some trouble noticed in swallowing, especially water; slight derangement of the bowels, tending toward constipation; more or less tympanitis present; retention of urine, — for a few hours at least; head drawn back so the end of the nose tends to assume a position somewhat on a line with the neck. The death loss is less than 10%, but in those that do not recover the market value is depreciated to a very great extent because of the faulty gate the animal assumes after an attack of this disease due to atrophy and contraction of certain muscles, or certain groups of muscles. It seems that the flexor muscles of the limbs especially are more often affected than the extensor, and in almost all the cases some of these deformities are likely to remain permanent. The flexors of the limbs are liable to contract and cause volar flexion of the fetlock. The elevators of the head are also likely to become affected, so as to cause the head to have a poky appearance; that is, it is carried out from the body.

" After one of these attacks, the colt will remain down from one to three weeks and will then continue to improve for a period of one year, but seldom, if ever, makes a complete recovery.

" LAKE CITY, MINNESOTA." " DR. C. S. SHORE.

disease followed intimate contact with persons with old infantile paralysis, often of many years' standing. The latter cases seemed to be unworthy of mention in a serious report, but after consultation with our advisory board it seemed worth while to allude to the matter for what it is worth, e. g., a child of two and one-half was not, so far as known, in direct or indirect contact with any acute case, but was, previous to his attack, daily fondled and cared for by a girl of fourteen paralyzed twelve years previously. On Aug. 14, 1909, he developed the disease. The board would not wish to be understood as advocating the view that chronic cases were sources of infection, but the frequency of such histories make it proper to mention the matter as one worthy of following up, although the general history of other diseases caused by a filterable virus would make it seem unlikely.

Instances of what would appear to have been contagion occurred in 35 out of 150 cases. They may be analyzed as follows:

Instances of Contagiousness.

	Cases.
Certain direct contact with acute case,	14
" " " " abortive case,	1
" " " " chronic case,	14
" " " " both acute and chronic case,	2
Certain indirect contact with acute case by third person,	4
Total,	35

The contact was so intimate between the cases, and so constant, that there is no sure means of determining the day of the illness on which the sick child gave the disease to the other, or, in other words, the period of incubation in the recipient.

Families with more than One Case.

134 families with 1 case.	
7 " " 2 cases.	
1 " " 3 cases.	
Total,	142

Cases among the Acquaintances of Patient.

(*a*) In 22 instances there occurred one other acute case, either shortly before or after.

(*b*) In 2 instances there were 2 acute cases each among acquaintances.

(*c*) In 2 instances, 4 acute cases each.

(*d*) And in 1 instance there were 6 acute cases.

(*e*) In 13 instances there was 1 chronic case each among the acquaintances of patient.

It is not demonstrated that contact necessarily took place between these individuals.

As bearing on the question of contagion, the places to which visits were made within a month before the attack was investigated.

Places Visited by Patient before Attack.

(*a*) No history of visits known, 42; (*b*) Revere Beach, 38; (*c*) City Point, 18; (*d*) Savin Hill Beach (Dorchester), 15; (*e*) Boston, 12; (*f*) Nantasket, 11; (*g*) Winthrop Beach, 8; (*h*) Dorchester Beach, 6; (*i*) Gloucester, 5; (*j*) Dewey Beach (Charlestown), 5.

(All these places were known to be infected areas.)

(*k*) Three other towns were visited by 4 cases each; of these 3 towns, 2 were known to be infected areas. (*l*) Eight other towns were visited by 3 cases each; of these 8 towns, 7 were known to be infected areas. (*m*) Ten other towns were visited by 2 cases each; of these 10 towns, 7 were known to be infected areas; (*n*) Forty other towns were visited by 1 case each; of these 40 towns, 25 were known to be infected areas.

Institutions for Children.

It was suggested by the advisory committee that it might be worth while to look into the prevalence of the disease in asylums, etc., where healthy children lived and were removed from the ordinary conditions of street life, many of which institutions were in the midst of infected districts. Forty-five such institutions were investigated where 3,600 young children lived. Only one child of the 3,600 developed the disease and this was under such remarkable conditions that the case may be mentioned.

E. R. (age two years and four months) entered the St. Mary's Infant Asylum in Dorchester on Aug. 28, 1908. In February, 1909, the child had measles and was taken to the South Department of the Boston City Hospital. No other sickness since becoming an inmate of the asylum.

On Sept. 30, 1909, the child had a typical attack of infantile paralysis; the diagnosis was made by the attending physician and confirmed at the Children's Hospital. Partial paralysis of one leg still persists.

This child is one of a class of walking children in the institution numbering in all 40. At the time of his illness, 2 or possibly 3 other children suffered from slight vomiting and diarrhea. Nothing else remarkable.

This child lived as regular institution children do, playing with his 40 companions on one floor and one porch.

The child never left the institution after he entered save to go to the City Hospital at the time of the attack of measles several months before. No one had visited the child or sent food, toys, etc., for several months before onset.

During the month of September only 6 new children were admitted to that part of the asylum. None of these had any illness of any sort.

The child, at the time of onset, showed no marks or bites or wounds. His diet was that usually given in an asylum for children, viz., mashed potatoes, meat juices, soups, bread and milk, oatmeal, and, very rarely, fruit. The children sleep sixteen in a room and all eat in the same dining hall.

The child was not isolated during his illness and no other cases occurred.

CONDITIONS, GENERAL AND SPECIAL, PRECEDING THE ATTACK.

The general and individual conditions preceding the attack are shown in certain matters in the following tables:

Swimming or Wading.

The frequency with which swimming or wading was mentioned as an antecedent in previous years

attracted our attention and was embodied in a question on our blank. Nearly half of the cases had been swimming or wading in water contaminated by sewage shortly before the onset of the disease.

Out of 150 cases, 62 were swmiming or wading just before onset.

Insect bites or stings, 35; wounds, 13; sore throat, 42; diarrhea, 35; otitis media, 2; coryza, 4; measles, 1; pin worm, 1; bronchitis, 1.

Ninety-three had one or more of the above possible sources of infection; 57 had no such history. Total, 150 cases.

INCIDENCE OF THE DISEASE.

Sex: 363 males and 263 females were affected.

Age: By the figures it is seen that the incidence is greatest between the ages of two and three. After ten years of age the chart deals only with ten-year periods and the average number of cases per year only is represented.

In the chart of age periods it is shown that only 7% of the cases occur in the first year of life, but 71% of cases occur in the first five years and 87% of cases in the first ten years.

PROGNOSIS.

Recovery Rate in 628 Cases.

In answer to the question, "Has paralysis entirely disappeared?" The replies were as follows:

Yes,	62	10.8%
No,	404	
Partially,	61	
Death,	51	
Not stated,	50	
Total,	628	

This table is intended to emphasize the fact that what appears to be recovery in the eyes of the family physician occurs more frequently than is generally supposed, 10% of such cases being reported. This led to a closer investigation of the recoveries in the 150 cases carefully investigated, and it was reported by the investigators that 25 of these (16.7%) had wholly recovered. This report was not accepted and the investigators were sent again to these children, and each child was stripped naked and the separate movements of ankle, knee, hip, spine, abdomen and arms were separately tested. From this careful examination it is sure that 25 children out of 150 have recovered since the disease in 1909. The following tables deal only with these 25 cases:

Age of 25 Recovered Cases.

So far as one may generalize from these few cases, it would seem that the average age of the children was higher than in the cases in general.

Age.	Cases.
1 year,	3
2 „	1
3 „	5
4 „	5
5 „	2
6 „	4
7 „	1
9 „	1
10 „	1
14 „	1
21 „	1
Total,	25

Onset.

The character of the onset was mild in 6, moderate in 17 and severe in 2.

Evidence of Paralysis.

The presence of paralysis in the beginning is vouched for by the attending physician in 23 cases and by the family in 2, and the distribution of paralysis was on the whole fairly extensive, as shown by the table.

EXTENT OF PARALYSIS IN 25 RECOVERED CASES.

One thigh and leg,	4
Both thighs and legs,	8
Both thighs,	1
One leg,	2
One arm,	1
One leg, arm and back,	1
One leg and back,	1
One thigh, leg, arm and forearm,	1
One arm, forearm and cervical region,	1
Cervical region,	4
Indefinite staggering gait,	1
Total,	25

The extent of the paralysis, therefore, did not differ essentially from that of the whole group presented above.

DURATION OF PARALYSIS IN 25 RECOVERED CASES.

Time.	Cases.	Time.	Cases.
3 days,	2	8 weeks,	8
1 week,	3	12 weeks	4
2 weeks,	3		
3 „	2	Total,	25
4 „	3		

Tenderness in Recovered Children.

It was thought that such cases being slighter might show less tenderness in the acute stage, but the tenderness was about as frequent as in the severer cases.

Pain or tenderness in the acute attack existed in 19 out of 25 recovered cases.

Duration of tenderness.	Cases.	Duration of tenderness.	Cases.
2 days,	1	3 weeks,	1
3 „	1	4 „	3
7 „	6	6 „	1
10 „	1	8 „	2
2 weeks	2	12 „	1

The statement may, therefore, be made that in the whole group of 628 cases, 10.8% were reported as wholly recovered; that in the smaller group of 150 cases, 16.7% are known to have recovered, and that a study of character of onset, distribution and tenderness in these cases gives no means of distinguishing them from other cases at the time of the attack.

PREVENTION.

In the matter of prevention of the disease in Massachusetts, in November, 1909, it was made one of the notifiable diseases, like scarlet fever, etc. In a recent circular addressed to physicians it has been advised by the board that such cases should be quarantined and that urine, stools and sputum should be disinfected, and we have called attention to the existence of abortive cases as probable sources of contagion.*

CONCLUSIONS.

These data are presented as a report of progress in an investigation which will be continued, and no conclusions are drawn from them.

That the effort of the state Board meets with general approval is shown by the fact that the following resolution was adopted in Washington, on May 5, 1910, by the American Orthopedic Association and the American Pediatric Society.

"It having been shown by recent epidemics and investigations connected with the same that epidemic infantile spinal paralysis is an infectious, communicable disease which has a mortality of from 5% to 20%, and that 75% or more of the patients surviving are permanently crippled, state boards of health and other health authorities are urged to adopt the same or similar measures as already adopted and enforced in Massachusetts for ascertaining the modes of origin and manner of distribution of the disease with a view to controlling and limiting the spread of so serious an affection."

What the course of the disease may be in 1910 in Massachusetts cannot be predicted. It would be expected from the history of the disease that a year of comparative immunity in the state as a whole would follow the great prevalence of the disease in 1909 and it is, therefore, disappointing to find 22 cases reported in the first five months of 1910, as against 15 cases for the same five months in 1909. Whether this means merely an increased attention on the part of the profession or a really increased prevalence of the disease, time alone will show.

The object of the inquiry in 1910 will be twofold.

First, the formulation and classification of early symptoms and types of the disease with especial reference to early diagnosis and, second, a study of the conditions under which contagion seems to occur, with a continued search as to the mode of entry of the virus into the body.

The medical profession must remember that the Board of Health acts only as the agent of the profession in assembling the data provided by them, and depends on them for the same willing co-operation that it has met and is profoundly grateful for in the past.

The report for 1910 will be what the profession makes it and the board is anxious not only for the prompt and full report of typical cases, but also for notification of suspicious and atypical cases which are possibly of the abortive type and a most important link in the chain of evidence.

* In a recent communication, Flexner and Lewis report that a 1% solution of peroxide of hydrogen in perhydrol has been found to destroy the virus. In view of their belief that the entrance of the virus is probably by the respiratory tract, the use of a nasal douche of this character would seem advisable.

Clinical Department.

BILIOUS ATTACKS IN CHILDREN.*

PHILIP S. POTTER, A.B., M.D., NORTH ADAMS, MASS.

IT was with some hesitation that I chose this very common ailment as the subject of my paper rather than something of a research nature, but lately, in reading Dr. George F. Still's book,[1] this chapter deeply impressed me. For the term "bilious attack," while belonging to popular rather than to scientific phraseology, and conveying the idea of a simple digestive upset, may have a much deeper significance than it implies. He strikes the keynote when he says, "Herein lies the danger of a vague term like this; it has a misleading sound of innocence which may inspire an altogether unjustified feeling of security."

When we see a child with fever, vomiting, headache, constipation and perhaps some abdominal pain, and having probably attended this same child several times before with the same set of symptoms, are we justified in telling the mother that it is only a "bilious attack?" While, indeed, it may be nothing more than this simple term implies, nevertheless, there are other conditions which we should always have in mind.

APPENDICITIS.

In every "bilious attack" this possibility should be foremost, for if unrecognized, very serious consequences for the little patient may develop. The classical symptoms as seen in the adult may be very slight in the child. So slight have they been at times that nothing was thought of them, and after several so-called "bilious attacks" there came a time when all the symptoms were intensified, and a laparotomy showed the true state of affairs. Moynihan[2] says he has long recognized that "bilious attacks" of children — the sharp abdominal pain, headache, vomiting, languor, brief malaise, often associated with constipation, and ascribed to an unwholesome meal — culminated sometimes in a flagrant, and obvious attack of acute appendicitis for which an operation then or at a later stage of the disease was performed. After the loss of the appendix, no more was heard of the "bilious attacks," which before had been so frequent.

In one of Dr. Still's cases, a girl nine years of age, had been subject to "liver attacks" for four years; there was vomiting and some slight pain in the abdomen, but the attacks were so slight that the mother had been told by her doctor just to give the child a dose of calomel whenever the attack occurred; then a more severe attack than usual happened; at first, as before, it was called a "bilious attack," but it soon became evident that it was serious, a laparotomy showed not only a perforated appendix, but an encapsulated abscess with dense fibrous matting which must have been the result of previous attacks of appendicitis.

In another case, where the appendix showed considerable inflammation and ulceration of its wall, there had been no vomiting and the temperature had not been above 100° F.

In all cases of a history of bilious attack a careful examination of the child's abdomen should be made, and if possible made at the time of the attack.

RECURRENT VOMITING.

Sometimes preceded by a few prodromal symptoms such as anorexia, malaise, irritability, headache and dark rings under the eyes, there is a sudden onset of vomiting without apparent cause, lasting from one to six days, and then disappearing as quickly as it came. The child now regains its normal condition, and then again anywhere from two to six months passes through an exactly similar attack, when the condition is easily recognized.

During the attack the constant cry for water, with its immediate rejection, forms indeed a pitiful picture. As little or no fluid is retained in many of these cases, the tissues soon become drained of water, and as a result emaciation is rapid and accompanied with marked prostration. Moderate fever, which is almost always present under ten years, occurs early in the disease and is continuous for two or three days, then becomes subnormal. The constipation which precedes the attack now becomes obstinate. The breath has a peculiar sweetish odor. The urine, which is scanty and high colored, is strongly acid and contains indican; acetone and diacetic acid. The urates are increased and the xanthin bodies in great excess.

While Snow[3] thinks it is possible that some cases are the result of an intermittent form of hypersecretion of highly acid gastric juice, Rachford considers this rather a symptom and not an etiological factor. Lately Comby[4] has become very much impressed by the idea of appendicitis being an etiological factor. In 100 of his cases, 40 clearly showed appendicitis as the cause, and 5 a probable cause. In 3, appendectomy had no effect on the disappearance of the attacks. This idea is already gaining much ground among surgeons.

In quoting the following case I must confess that I am still in doubt as to whether I have a true case of recurrent vomiting or not.

* Read before the Onondaga County Medical Society, Syracuse, N. Y., May 10, 1910.

J. C., five years old. Father died of nephritis one year ago. Mother healthy but of a nervous disposition. First and only child; breast fed for fourteen months, at which time supplementary feeding was begun. The development was normal, and the boy has always been healthy except somewhat nervous. Two weeks ago he had his adenoids removed under ether anesthesia. Was sick all day and vomited a great deal. This soon ceased and five days later he began to vomit again, vomiting every little while. He cried a great deal for water. Small sips were given him, but it would immediately return. He has always had some tendency to constipation, but for the last four days he has been very constipated. His mother said the movement which took place after a suppository was pale, foul and contained much mucous, also that the urine was much diminished and dark.

His physical examination showed nothing out of the way except for lively patellar reflexes and a peculiar odor to the breath. The temperature was normal, pulse strong but intermittent. The urine was 1034, strongly acid, very abundant urates, no albumin or sugar. There was a slight amount of indican, acetone and diacetic acid.

At the time, not considering this a case of recurrent vomiting, but rather an intestinal intoxication, he was given high rectal salines and put on commercial buttermilk. Vomiting ceased immediately, the peculiar odor of the breath cleared up and he made a prompt recovery.

Arguing that an acetonemia which implies a diminished alkalinity of the blood bore a direct casual relation to the vomiting, Dr. Edsall suggested large doses of soda bicarbonate in the treatment. This acts almost as a specific in the prevention of the attacks and undoubtedly curtails attacks if given during the first few hours after the onset.

If it can be retained, 15 gr. in two teaspoonfuls of water with 5 or 10 drops of brandy is given every hour until six doses have been taken, then every two hours. If not retained, it is given by the rectum 2 drams of the soda in half pint of water.

In the preventive treatment, 10 gr. of the soda bicarbonate is given three times a day, instructing the mother to give it oftener if an attack threatens, and if vomiting begins, to give it every hour.

RECURRENT PYREXIA.

This term, suggested by Dr. Still, represents a condition sometimes called by the parents "bilious attack" and is thought to be closely akin to recurrent vomiting, occurring at intervals of weeks or months five or six times a year, and due to some auto-intoxication, allied to if not identical with that which produces recurrent vomiting.

The premonitory symptoms resemble those of recurrent vomiting. The onset is sudden, the fever running up quickly to from 102° to 105° F, remaining up, except for slight remissions for a week to ten days, and then within twenty-four to thirty-six hours quickly falling to normal. If there is vomiting, which is not always the case, it is very much like that of recurrent vomiting.

During the attack, the bowels are constipated and the stools pale. There is a slight headache. The pulse and respiration are increased. There is an absence of physical signs except occasionally a few rales in the chest. When there is no vomiting, these attacks with an abrupt rise of temperature, accompanied by rapid respiration and pulse, have been diagnosed as influenza or pneumonia, but after the patient has had several attacks of influenza or pneumonia every two or three months for several years, then we realize we are dealing with something else.

Dr. Still believes that the significance of these attacks are by no means clear and that they do not have the same significance in all cases. In some a dose of calomel has stopped the attacks; in others, while there has been a thorough cleaning out of the bowels, the pyrexia has continued, yet he believes it is due to some auto-intoxication from the bowel.

In the treatment of these cases the starches and sugars are excluded and calomel given, also arsenic to reduce the nervous excitability, as most all of these children, as in recurrent vomiting, are of a nervous type, a point to be remembered in their management.

MENINGITIS.

When we encounter a child with vomiting, headache and constipation, we are unable for the first day or two to decide whether we are dealing with a "bilious attack," a beginning of a recurrent vomiting or the first indication of a tubercular meningitis. This is mentioned merely to emphasize how easy it is to mistake the early symptoms for what the parents might take for a slight "bilious attack." I recall a case which I saw three years ago, in an infant under a year, who had some vomiting and constipation, but none of the signs of meningitis. It was thought to be a feeding case needing a rearrangement of the proteids, fats and carbohydrates. This was done without any results. About four days later the baby developed, if I remember correctly, a slight stiffness and rigidity of the neck, had a convulsion and died. Tubercular meningitis was found at autopsy.

MIGRAINE.

This is not uncommonly spoken of as a "bilious attack," and while not very frequent in childhood, occurs occasionally between five and twelve years of age. Here again we have the headache, vomiting, constipation and fever, differing in the latter respect from the migraine of an adult. This, again, may be akin to recurrent vomiting, for Rachford has noted in several cases the replacement of recurrent vomiting by attacks of migraine in adult life.

Beginning with a few prodromal symptoms such as burning and tingling of portions of the body, flashes of light before the eyes, dizziness and ringing in the ears, the attack is ushered in by an intense throbbing unilateral headache which increases in intensity, and followed in a few hours by vomiting, which usually marks the climax of the paroxysm. This is followed by a deep sleep, which is one of the most characteristic symptoms, the child waking up in six or eight hours free from pain. The temperature may

or may not be elevated, but during the paroxysm generally runs up from 1 to 4°, becoming subnormal following the sleep.

In a young child the pain in the head may be almost entirely absent, and frequent vomiting with nausea is the prominent symptom.

These attacks of migraine last from a few hours to two or three days, and occur at regular or irregular intervals. In some children it has been observed to recur weekly.

The urine is not unlike that of recurrent vomiting. It is highly colored, highly acid and of a high specific gravity, and contains an excess of xanthin bases. In some instances acetone and diacetic acid have been found.

The urea is diminished and ammonia increased. During the paroxysm there may be a slight amount of albumin.

An intense throbbing unilateral headache, increased by light or noise, associated with nausea, and followed by a deep sleep and an awakening free from pain, is not characteristic of any other type of headache.

RENAL VOMITING.

Renal vomiting due to hydronephrosis, pyelitis, or renal calculus may at times be considered, at the outset, nothing more than a bilious attack.

Again I would like to quote one of Dr. Still's cases to illustrate this. Walter F., six years old, was stated to have "bilious attacks" for the last three years. Every three or four weeks he had an attack of vomiting, usually lasting a few hours, but occasionally lasting several days; in a recent attack he had been sick ten days, not being able to keep down a drop of water; he was feverish during this time, constipated and had some pain in his abdomen. This pain was always on the left side, and on palpating the abdomen one found a rounded smooth tumor almost the size of a man's fist in the left lumbar region, over laid by bowel. He was admitted to the hospital and after a few days the tumor suddenly disappeared completely. The amount of urine passed on that day was about 4 to 5 oz. in excess of what he had passed on other days. The tumor did not reappear while he was in the hospital, so after remaining there a fortnight he was sent home. After a short time he reappeared with a history that another attack of vomiting had begun five days previously, he had had some pain in the left side of the abdomen, and the vomiting had been continuous. On palpation the tumor was now felt as previously, but not so large. He was readmitted and the tumor increased slowly in size, but the boy had no pain or vomiting and seemed well; eight days after admission the tumor completely disappeared again and as before it was noticed that he had been passing about this time a larger quantity of urine than usual. On operating, there was found a dilated pelvis with a valvular kink of the ureter at its entry into the pelvis.

OTITIS MEDIA.

Another remote possibility to keep in mind is an acute inflammation of the middle ear, especially in infants, who suddenly become fussy, vomit and run a temperature.

If one is not in the habit of using an ear speculum, and does not get evidences of pain and tenderness around the ear, his attention may become directed away by some of the reflex symptoms.

Although the vomiting is not characteristic of that in a "bilious attack," yet there have been times when, this symptom being to the front, and coincident with some indiscretion in feeding, the possibility of ear trouble was overlooked and the attack called a "bilious attack."

Case I. R. P., four years old. Has always been poorly fed since supplementary feeding was begun. For the past week he has been having a bronchitis. The day before I saw him he had eaten a great deal of chocolate candy. In the middle of that night he was found wandering around the house. He was put back to bed and then began to vomit frequently. His mother said he brought up a good deal of mucous and bile. She thought it was only a bilious attack due to the candy he had eaten. The next day the vomiting continued, not even small sips of water being retained. He was constipated. On examination he presented an apathetic condition, the face was flushed and the tongue brown and dry. There was a grunting respiration, a slight stiffness of the neck and lively patellar reflexes, no Kernig. The abdomen was negative and the chest showed only a few moist rales posteriorly. The temperature was 104° F., pulse 144, respiration 44. The tympanic membrane of the left ear was decidedly reddened; that of the right slightly so. The parents refused a paracentesis; local treatment was instituted. That night he had a very comfortable night and the next morning the temperature had dropped to 101.3° F., the vomiting had ceased and the child was decidedly better. The following day the temperature came to normal.

Case 2. This child, who was one and one half years old, was just recovering from scurvy. He was cutting his lateral incisors and has been having a slight cold for the past week. Lately has been much constipated, the movements consisting of small hard balls. Christmas Day he was allowed some chicken and blueberry pie for the first time. That night he became very fussy and began to vomit. He was very restless and kept rolling his head about and crying out sharply. The mother thought he had a "bilious attack" due to the chicken and pie.

He appeared very ill; face was flushed and the pupils dilated. There was a rapid grunting respiration, a very rapid pulse, and a temperature of 105° F. The examination of the chest was negative. The left drum membrane was fiery red. A paracentesis was done; also the removal of a large mass of adenoids. That afternoon the temperature dropped to 100.2 and the child became more playful. The following morning the temperature rose to 104.4 and the child appeared very ill again. The other ear was suspected, but on examination it proved to be normal. As his bowels had not moved in two days he was given a high enema, with the result of a very full and very foul movement, which contained mucous. The temperature now returned to normal.

DIGESTIVE DISTURBANCES.

These, the most common and of the least significance of what we call "bilious attacks," may be put under two headings:

1. Gastric indigestion.
2. Intestinal Toxemia.

GASTRIC INDIGESTION.

These children, after some indiscretion in eating, feel tired and out of sorts, and those old

enough complain of headache and stomach-ache. This is followed by sudden repeated vomiting. The tongue is coated, the breath offensive and the bowels generally constipated, although there may be a relaxed condition of the intestine. There is a slight temperature of 101° or 102° F.

Fred D., two and one-half years of age. Had always been healthy and strong until he was one and one-half years old. At this time the parents became less careful as to his feeding. He has been more or less constipated since birth. About three months ago he was given some grape-fruit just before his milk feeding. This was followed by an acute upset, and, according to his mother, his stomach would retain nothing for five days. He is a very nervous child, always has dark rings under his eyes, and sleeps poorly, awaking at the slightest sound and lying awake half of the night. He has nocturnal enuresis. Since his last attack, his breath has been foul. There has been a slight loss of weight, and lately he has been passing some mucous in his stools.

The morning of the day I saw him, he was given some peppermint creams by his father and then went for a long sleigh ride, the morning being very cold. On his way home he began to vomit copiously and became quite prostrated.

I found him very drowsy and very nauseated. The skin was cool, and the pulse rapid and weak. The temperature was 97.2° F., but within an hour it arose to 100. 1. The stool obtained by enema was well digested but foul and contained considerable mucous. The urine was very acid, the indican and urophain greatly increased. After the next forty-eight hours the vomiting ceased and the indican disappeared, the child having been put on buttermilk.

INTESTINAL TOXEMIA.

While components of dead bacteria furnish a certain amount of poisonous proteins, and living bacteria in the intestine excrete ferments or toxins, substances produced by bacteria from the culture media are possibly the most important source of intestinal intoxication, the virulence of the ptomaines formed depending not only upon the micro-organisms, but upon the character of the food material in which it is growing.

The products formed during the process of putrefaction are indol, skatol, phenol, cresol, leucin, tyrosin, ammonia and hydrogen sulphide; also volatile fatty acids, oxalic acid, uric acid and the xanthin bodies. The most important of these bodies is indol, varying amounts of which we find in the urine in the form of indican, whose etiological relationship to nervous symptoms has been demonstrated, although the absence of indican does not rule out intestinal intoxication, since severe forms have occurred in which indol was not an etiological factor.

Rachford [5] thinks that these severe albuminous fermentations are more common in a child than in the adult. He bases his view on the fact that the Hcl. formation of the stomach is not so well developed in the young child, and, therefore, not as capable of exercising the same control in preventing intestinal fermentation; also that the filtering function of the liver is not as well carried out as in the adult.

As an example of the severe nervous symptoms due to the absorption from the intestinal canal, I would like to quote the following case.

This occurred in a five-year-old Italian child who lived in a very ignorant family under very filthy conditions. The father, who was a market peddler, lost a child two years ago from meningitis. From what information I could obtain, the child was in the habit of eating some of the left-over slightly spoiled fruit. When I first saw him, so profound was the intoxication that it strongly suggested meningitis. He was semi-conscious, being aroused with difficulty. The temperature was 105° F., the respiration increased, as was the pulse, which was full and bounding. Nothing was found in the lungs. His face was flushed, pupils irregular, and responding slowly to light. There was slight rigidity to neck, increased patellar reflexes, marked Kernig's. There was no Babinski or ankle clonus. At times there were quick strong contractions of the muscles of the lower extremities. Rectal examination showed the lower bowel packed full of feces. Lumbar puncture was offered, but the father refused to let it be performed.

This child had been ill three days, the onset being ushered in by vomiting, headache, slight fever and some abdominal pain. The bowels had moved slightly every day. The first day his physician gave him a good cleaning out, with the result of a drop in the temperature and an improvement in all of the symptoms. As soon as the bowels became costive, the temperature went up again, so that at the time I saw him his temperature was 105. The movements now obtained from day to day were very foul, and contained a good deal of mucous. With a continued cleaning out, the nervous symptoms disappeared and he made a good recovery.

In conclusion, while the parent's tale of a "bilious attack" may mean the most innocent of digestive upsets, their diagnosis must be carefully sifted and a thorough physical and clinical examination made and the other possibilities excluded.

THE ETIOLOGY OF COMMON COLDS.

BY A. COOLIDGE, JR., M.D., BOSTON,

Assistant Professor of Laryngology, Harvard Medical School; Physician for Diseases of the Throat, Massachusetts General Hospital.

IN an editorial in the JOURNAL of May 26 [1] on the "Prevention of Common Colds," it is assumed that this term means an acute bacterial infection of the mucous membrane of the upper respiratory tract. With this assumption I am in sympathy, more perhaps because I think that in case of dispute it is the proper side to take, than because it is absolutely accurate. The term "cold" is a popular rather than a scientific term, and as such means different things to different men. As expressing a pathological condition it has long been abandoned by the medical profession. Its use is still forced upon the family practitioner by his patients, but as the word is no longer orthodox, he can twist its meaning to suit the occasion.

To many the word "cold," at least as far as it

[1] Vol. clxii, p. 718.

applies to the nose, is associated with a group of symptoms commonly called coryza. For instance, we have what is known as "rose cold," which is not a bacterial infection. The question is then one of a better definition of an ancient but still active word, which cannot be eliminated from the intercourse between physician and patient, even if it were desirable to do so.

A similar uncertainty of definition hangs over such words as "rhinitis" and "pharyngitis," which are often used to include not only true inflammation, but any disturbance of function or secretion or sensation which cannot be classified under some more definite pathological heading. With advance of knowledge a constantly increasing proportion of cases are found to be dependent upon some local lesion or definite infection or general condition which makes their classification and description more exact; there still remain, however, a large number of cases in which the etiology is obscure and the local appearances misleading. Among the acute disorders of the nasal chambers we may distinguish some as due to infection and others as arising from a local irritability and vaso-motor disturbance. A type of the first class would be a rhinitis where the infecting organism is known, and of the second the coryza induced in some persons by the pollen of certain plants or by sitting in a draft. In some cases both of these etiological factors may exist, and in many more it may be uncertain or a question of individual opinion whether an infection or some form of local or systemic irritation is the cause of the symptoms.

The more definite processes, such as diphtheria on the one hand and hay fever on the other, are no longer classified as simple acute rhinitis or "cold in the head." Among those that remain it is important to distinguish as far as possible whether we are dealing with an infection or with some systemic or local irritation.

Among the varieties of acute rhinitis or cold, there is one form which it seems to me is so common and constant in its symptoms that it should be classed as a distinct and definite disease. Briefly, the symptoms are as follows: The first suspicion on the part of the patient that he has such a cold starts from an irritation or sensation in some spot, often the nasopharynx, occasionally the larynx, nose or tonsil. During the next few hours this irritation extends to neighboring regions, and this continues perhaps for a few days, but the amount of its extension varies in different cases. It may involve the nose, the sinuses, the pharynx, the larynx, the trachea and the bronchi, rarely the stomach, but it may spare any of these parts. The local appearances are in most cases less marked than the severity of the symptoms would suggest. There is an increase in redness of the mucous membrane involved, and other signs of inflammation, generally of a mild type. In the nose the turbinates become engorged during the symptoms of coryza, and abundant watery secretion is seen. In the pharynx the mucous membrane becomes red, especially about the so-called follicles and the faucial pillars. In the larynx and the trachea there is a distinct reddening of the mucous membrane, especially in the latter. The vocal cords may or may not escape. But none of these local appearances are really characteristic; the diagnosis must largely be made from the patient's symptoms and history.

This common form of cold runs a more or less definite course. It is generally possible to trace its extension from one region of mucous membrane to another. Although the symptoms connected with it are dependent upon the region involved and the severity of the attack, these symptoms do not suddenly arise and suddenly disappear, as is often the case with vaso-motor rhinitis. It appears to spread between persons in close contact with each other, and with an incubation period of from two to four days. It occurs less frequently in summer than at other times of the year, and is rather more common in children than in adults, although persons vary in the frequency and severity of the attacks. The process is essentially an acute one, the period of extension seldom lasting many days, and all symptoms and appearances sometimes disappearing in a few hours or days. During this period there is seldom any rise in temperature, no formation of pus nor increase in the number of bacteria to be found. In some regions, however, notably the nasal and accessory cavities and the bronchi, there may be a purulent invasion following the acute stage, suggesting the result of local failure of resistance, due perhaps to a disturbance of function of the self-cleansing ciliated mucous membrane. This second or subacute stage is characterized by the formation of mucopurulent secretion containing different micro-organisms, it varies much in severity and length, and may lead the way to serious trouble. During the primary stage there is a varying amount of local and general discomfort depending upon the extent of the trouble and the idiosyncrasies of the patient. When a purulent stage follows, the temperature and the severity of the disease depend upon the locality and extent of the secondary complications and the invading organsim.

No specific micro-organism has been found to explain the cause of this most common form of acute cold, but this is equally true of other diseases whose nature is evidently contagious. As the community and even a majority of the medical profession insist on seeking some recent exposure to weather as the cause of each case as it arises, the sometimes obvious contagion is overlooked. The common belief is that the start is given to the process by some chilling of the skin, as a result of imprudence in exposure, or in dress, acting in some way through changes in the body temperature or through the nervous system; or that exposure frequently gives a chance to some pathogenic organism which is waiting for the opportunity. While this latter is perhaps sometimes true in such cases as an already existing bronchitis, I believe that a typical cold never starts in this way.

There is much evidence tending to show that these colds are often directly contagious. If we can prove that a definite pathological process is

often due to contagion, the same process is probably always due to contagion.

It is a matter of common knowledge that epidemics of simple colds may occur. Even more common is the observation that when they appear in a large family of children they go through the family or even a school. Families of children often remain in the country all summer entirely free, but soon after beginning school start a series of colds which spread to other members of the household. If, however, a cold should start in the middle of summer it may, in the same way, go through a family or several families. These cases do not begin all at once, as would be expected if they were due to the weather, but in sequence.

Evidence may be cited also that where no chance for contagion exists this usual form of cold does not arise from exposure. Nansen mentions that on his Polar expedition no one ever had a cold. In the more recent expedition to the Antarctic under Shackleton, Dr. Marshall reports that the only suggestion of colds in the head which occurred was on opening a bundle of blankets, when symptoms of acute rhinitis appeared in the hut, but soon subsided after exercise in the open air, — obviously a vasomotor and not an infectious rhinitis. I have notes of reports of other long voyages where, in spite of exposure, physical weakness and unhealthy surroundings, acute colds did not appear until after the vessel reached port. I have been told by the captain of a whaler that the people in Greenland never have colds except when it is brought by a ship.

My own experience tends to agree with those who have observed that colds have an incubation period of from two to four days, that they remain contagious for several days and that the acquired immunity is short. Also that the disease is carried especially by sneezing, coughing, embracing and speaking at close range, possibly by towels and other utensils, but only for a short time, and that much can be done to prevent its spread by acting along these lines. It spreads more frequently among children because they are in more frequent contact with each other than are adults. To prevent colds a little care given to avoiding close contact will accomplish much more than a great deal given to details of clothing and exposure to weather.

The susceptibility of different persons varies greatly. There would appear to be sometimes either a lack of general resistance to the infection or a local susceptible area. Perhaps the larger amount of lymphoid tissue in the pharynx of children increases their susceptibility. I have not been able to prove that there is any relation between a person's susceptibility to colds in the head and his general health and strength.

In addition to the above-described form of cold, there are other types which, although having some symptoms in common, differ enough to make it probable that, although infectious, they are due to some other organism. These generally run a more prolonged course. They may be accompanied from the start by a purulent secretion and sometimes by rise of temperature. They are, as a rule, less contagious than the more common form. Epidemics in which acute rhinitis is a prominent symptom are various and not uncommon. It accompanies measles and other constitutional diseases. It may or may not appear in infection by the bacillus of influenza. The micrococcus catarrhalis apparently sometimes causes an epidemic of rhinitis and pharyngitis. In other cases of acute or subacute inflammation the staphylococci, streptococcus, pneumococcus or a diplococcus are probably the primary cause of the disturbance, certainly they are there in large numbers. Some of these organisms are common in healthy throats, and consequently acute attacks caused by them would have to be explained by a lowered resistance and would not appear as an epidemic. But in the more common form of cold the theoretical micro-organism which starts the process and carries the contagion has not yet been proved, and is probably none of these. If we may classify it as contagious we may assume the micro-organism.

The criticism that the personal experience of many, and the common belief of centuries, proves that a common cold is generally the result of exposure may be answered in different ways. Within a comparatively short time the accepted etiology of several diseases has been radically changed, and generally in the direction of assigning a definite cause to a definite disease. In one sense a " cold " is not a definite disease inasmuch as the term may be used to include various symptoms of vasomotor origin. But this is not the kind that is commonly meant when the word " cold " is used. Symptoms of vasomotor origin come on at the time of exposure, and their duration is dependent upon external conditions. They do not run a definite course extending from one region of mucous membrane to another, and they seldom lead to purulent secondary complications.

When we recognize more definitely the common type of infectious cold, and the differences between it and coryza due to vasomotor disturbance, we may classify the latter with hay fever and its kindred, and announce that a " real cold " is a contagious disease. I think that the community would gain much by this assumption. The objection to drafts and wet and cold in moderation which induces humanity to shut itself into air-tight inclosures is often due to an unwarrantable fear of " catching " just those diseases which are, in fact, communicated by sneezing, coughing and poor ventilation.

RED CROSS MINE WORK. — The American National Red Cross plans to introduce in the bituminous mining districts the first aid to the injured system which has been in use for several years in Pennsylvania. The Pullman Car Company has donated a car in which visits will be made to the mines throughout the country, and instruction will be given to employers and employees in the most approved first-aid methods. The railroads over which the car will travel have, with the sanction of the Interstate Commerce Commission, agreed to furnish free transportation, and it is expected that the work will be begun during the latter part of the month under the supervision of Dr. M. J. Shields. — *Med. Record.*

Reports of Societies.

THE AMERICAN NEUROLOGICAL ASSOCIATION.

Thirty-sixth Annual Meeting.

May 2, 3 and 4, 1910.

Monday Session.

(Continued from No. 1, p. 26.)

DISCUSSION.

Dr. J. K. Mitchell, of Philadelphia: How does Dr. Thomas justify the diagnosis of locomotor ataxia with knee-jerks still present? In the last year I have seen one case of tabes in which gastro-enterostomy was done and two cases in which operation was done for gastric crises and two in which gallstones were hunted for. Presumably in none of these cases did the surgeons take the pains to examine either the knee-jerks or the eye reflexes.

Dr. Philip Coombs Knapp, Boston: I must confess that theoretically I am somewhat skeptical about the results of operating upon the posterior roots for the gastric crises of tabes, because of the physiological fact that the nerve supply of the stomach is dependent very much more upon the vagus than upon the sympathetic. The success of Dr. Thomas's case, however, has led me to have another case which is very similar to his operated upon by Dr. Blake a day or two ago. In answer to the objection Dr. Mitchell raised to the diagnosis in Dr. Thomas's patient, I would say that in the last few years, as well as previously, I have seen a good many cases with pretty clear tabetic symptoms but with retained ankle-jerk.

Dr. Harvey Cushing, Baltimore: I am far from being in accord with Dr. Mitchell's statement that surgeons are a bad lot, especially in Baltimore. However, I would like to make an arrangement with Dr. Mitchell whereby I would turn over for his collection the list of cases of the kind he mentions of which I have cognizance, in return for the list of cases of brain tumor long treated for gastric headaches. Just a day or two ago a patient, a woman who had very persistent crises, with great pain, was transferred from the medical to the surgical side for operation, but when I saw her I decided to delay operation as she was absolutely free from pain. I do not think any surgical cases of disease reported after they have been done a month really convey a fair general impression as to what the author's results are.

Dr. Joseph Collins, New York: In the discussion the Association is liable to lose track of what they started out for, that is, the feasibility and advisability of this operation. I am very much in favor of the operation in cases that are intractable. Relative to Dr. Mitchell's question in reference to knee-jerks being present in tabes, I would say that in ten out of twenty cases of tabes the knee and ankle jerks are present. If this statement is not accepted by the Association, I will have the members define what they mean by tabes.

Dr. F. X. Dercum, Philadelphia: A man seen by me many years ago, long before we had resort to the examination of the cerebrospinal fluid and the Wassermann test, had frightful suffering, apparently crises of tabes, though the knee-jerks were retained. There was no marked disturbance of sensation anywhere, but there were markedly contracted pupils. The patient was a user of morphia, but on being persuaded to do without hypodermics forty-eight hours he had a good pupil which responded to light. In other respects the symptoms varied somewhat. There were symptoms of a gastric nature. I had Dr. Keen examine him and he excised a small gastric ulcer and the man recovered. We all meet with such distressing cases, and I believe that this operation promises something in an otherwise very serious affection.

Dr. Thomas: I am very sorry that Dr. Mitchell should have been disturbed by the patient having knee-jerks. I agree fully with Dr. Collins in saying we frequently make the diagnosis of tabes in the presence of knee-jerks and ankle-jerks. The reflex of the pupils was absent to light, although retained at first, and the man had marked hypertonicity which I thought was fully as important to tabes as ataxia, and I felt justified in calling it one of tabes. I made the Noguchi test and it was positive for syphilis. The count of the cerebrospinal fluid was not made. At operation there was a marked degeneration of the pia.

OCULOMOTOR PALSIES DUE TO VASCULAR CONSTRICTION IN CASES OF BRAIN TUMOR.

Dr. Harvey Cushing, of Baltimore: Oculomotor and particularly abducens palsies, more or less fluctuating in degree, often occur in cases of tumor and are included among false localizing signs. Various explanations have been offered for their occurrence. Contrary to the usual anatomical description, these nerves underlie the lateral branches of the basilar artery, which have a rubber band effect, and so constrict the nerves as to block their transmission of impulses. The condition is most apt to accompany tumors of the posterior fossa.

Tuesday Morning Session.

A NEW TYPE OF PRESSURE MYELITIS.

Dr. Graeme M. Hammond, New York: The description of this disease is based upon the study of seven cases which have come under the author's observation. The pathological conditions seem to consist of the development of an enormous amount of new bone tissue, which is spread over a number of vertebræ and adjacent rib ends, obliterating all articulations and giving the affected vertebræ and ribs the appearance of being one single piece of bone. The development of new bone also occurs within the vertebral canal and gives rise to compression of the cord, causing both sensory and motor symptoms, but eventually leading to the most intense rigidity of the entire voluntary muscular system below the level of the lesion. There was the gradual development of the "Bible back" or forward curvature of the vertebral column seen in spondylose rhizomelique, but in none of the cases was there any evidence of rheumatism.

DISCUSSION.

Dr. B. Sachs, New York: I have seen a number of cases that have offered some difficulties in diagnosis, particularly in trying to make the differential diagnosis between such conditions as described and a simple myelitis. Within the last few months I have had at Mt. Sinai Hospital, New York, two cases of absolute spinal rigidity. An x-ray picture was taken in one case and showed a condition very much like the one presented by Dr. Hammond. In this case, a man of about thirty-five, the rigidity of the spinal column was absolute, from the third or fourth cervical vertebra to the very end of the spine. In fact, in this case there was no movement possible of the body except slight movement of the head forward and a slight lateral movement of both sides. There were extreme contractures and atrophies. The man as he now lies in bed has his knees so completely contracted that

you can hardly put a hand between the posterior surface of the thigh and the posterior surface of the calf, the legs are locked together and there is absolutely no motion of any part of the leg, except of the toes. The atrophy is more extreme than I have ever seen it in any case of ordinary spinal origin. There is hardly a bit of tissue left; when you press the skin it seems as if you had the bone in the hand. So far as the diagnosis is concerned, I am not ready to suppose this represents an entirely new type of disease, although I do not want to deprive Dr. Hammond of the honor if he could prove it. I think these cases are closely related to spondylose rhizomelique type. I hope that in all these cases of mysterious spinal disease an x-ray picture will be taken, for nothing is more serviceable in case of mysterious spinal disease in reaching a diagnosis when medical signs are wanting.

DR. D. J. MCCARTHY, of Philadelphia: My feeling is that we are dealing, in these chronic cases of rigidity of the spine, with not only a factor involving the bone and cartilages, but an involvement of the spinal dura on its external surface, and this should be examined very carefully microscopically. It is more rational to suppose that here you have an extensive process it would more likely be due to inflammatory changes in the dura, a condition localized to one group of joints. The bone changes are secondary and are not the primary disease.

DR. WILLIAM G. SPILLER, Philadelphia: I have not quite understood from Dr. Hammond the distinction between the type he has described and that which Von Bechterew describes. Von Bechterew makes a distinction between his forms and those of Marie. There are in this connection two other kinds of disease. They are not likely to cause confusion in diagnosis, but they are interesting to mention. Eight or ten years ago Dr. Mills and myself reported a case of a man who was paralyzed and had rigidity of the spinal column. We found that the dura was firmly adherent to the bodies of the vertebræ throughout the whole course of the spinal canal, and in removing the cord it had to be cut away inch by inch. This could be recognized by the x-rays. In the past winter I have had an interesting case in a man who developed paralysis and exaggerated reflexes of his lower limbs. The disease gradually progressed upwards, involving his left arm and then the other arm, and the course of the disease was only a few weeks. I found a growth on the outside of the dura which under the microscope shows probably endothelioma. This is the first case I have seen of real endothelioma developing primarily between the dura and the bodies of the veterbræ.

DR. HAMMOND, closing: In regard to the case Dr. Sachs spoke of, I think there is no doubt that it is a case of spondylose rhizomelique; he has the muscle changes which go with such conditions. In none of my cases was there any anchylosis of the hip-joints, or atrophy. The rigidity was a muscular spasticity just as we see in a myelitis of the crossed pyramidal tract with the attendant symptoms of clonus, Babinski reflex and exaggerated reflexes. This persisted until rigidity had become great. All these cases die; not so the cases of spondylose rhizomelique; many of them live on for years.

I agree with Dr. McCarthy that the bone changes are secondary. In all the cases the first symptom elicited was the curvature and rigidity of the spine coming on three or four years before the first spinal symptom was apparent.

In regard to the changes of the dura spoken of by Dr. Spiller, in the only case I have had a chance to examine the dura it showed no adhesions. So I doubt whether adhesions of the dura have anything to do with the symptomatology of this condition. It simply seemed to me that on account of the increase in the bony tissue the spinal cord is gradually compressed and destroyed and these patients die. I do not think it tallies at all with any of the cases described by Von Bechterew. It may not be a new disease, but it is new to me and I have no doubt that, when attention is called to it, we will find a good many cases of similar type, but it is not that of spondylose rhizomelique.

CYST (POSSIBLY TRAUMATIC) OF THE SPINAL MENINGES REMOVED BY OPERATION, WITH RECOVERY OF THE PATIENT. REMARKS ON THE LOCATION OF THE CENTERS FOR TESTICULAR SENSIBILITY.

DR. CHARLES S. POTTS, of Philadelphia: A farmer, aged forty-two years, received a blow upon the back eighteen years before coming under observation. No serious symptoms were caused at that time. Two years before admission to the German Hospital (12–8–09) he began to have attacks of severe shooting pains in the left hypochondrium. During the attacks the lumbar muscles of the left side were thrown into spasm. At this time a girdle pain extending through the umbilicus was also present. A few months before admission first noticed difficulty in walking. Examination showed a very ataxic gait. Muscular power of the legs good, knee-joints, plus; ankle joints, plus. Babinski on the right side. The cremaster reflex was present on the left side but absent on the right. Abdominal reflex absent. Station poor, heel to knee test poorly performed; unable to recognize the direction of passive movements of the toes. An area of possible hyperesthesia and hypalgesia extending about four inches below the right groin. Both testicles completely insensitive. Sphincters normal. The laminæ of the sixth, seventh, eighth, ninth and tenth thoracic vertebræ were removed. A soft growth, pronounced by the pathologist to be a traumatic cyst, was found extending subdurally from the lower angle of the wound (first lumbar segment) upwards for about three inches. Complete disappearance of pain. Testicular sensibility returned and there was nearly complete disappearance of all the other symptoms.

DR. SANGER BROWN, of Chicago: I was struck, in reading over the abstract of Dr. Potts' paper, with the fact that the author spoke of centers for sensibility in the spinal cord. Now if one speaks of a center of sensibility I think he usually has in mind a group of bodies of neurons which preside over a particular function. This is well understood to apply properly to motor neurons. We have pretty well-defined and pretty well-demonstrated centers for motion, but we may safely say that in this sense there are no sensory nerve centers in the sensory nervous system. I think that is, strictly speaking, incorrect, though not uncommon, to speak of sensory centers anywhere in the central nervous system.

DR. POTTS, closing: I admit that the use of the word "centers" was not strictly correct. I afterward changed that to "spinal centers," which would be more nearly correct. Still there are in common acceptation sensory centers; they are made up of sensory neurons. In this case they would probably be in the first lumbar and lower dorsal segments of the cord. The nerves derive their supply from these particular areas; therefore, they are in a sense centers.

TUMORS AND CYSTS OF THE SPINAL CORD AND ITS ENVELOPES.

DR. CHARLES K. MILLS, Philadelphia: I will speak of the revival of interest in the question of spinal tumors and cysts, especially with regard to operative

procedure. Special attention has been attracted to the subject recently by contributions of Horsley, Spiller, Oppenheim, Krause, Bliss and others, who have particularly discussed the subject of chronic circumscribed meningitis in its relation to cystic formations and their surgical treatment. I will next present the histories of three cases of intraspinal disease. The first was one of tumor of the lower cervical region; the second was a cyst of the thoracic region similar to those which have been described under the designation of circumscribed serous meningitis; the third was a sarcoma involving the cauda equina and lumbosacral roots, and, to some extent, the cord. In addition to these cases several cases of intrapelvic tumor are reported with the view of emphasizing the differential diagnosis between spinal and plevic growths. The chief points of interest in the case of subdural cervical endothelioma were the exact localizing phenomena present—early pain at the upper pole of the growth as indicated by its distribution; the moderate but distinct atrophy and loss of power in the hands and fingers; compression of the pyramidal tracts as shown by paresis and exaggerated reflexes in the lower extremity, and impairment of the reflexes in the upper extremity on the side of the tumor. Anesthesia in the case was very slight and chiefly confined to tactile loss in the postaxial portion of the hand and forearm. After the operation contraction of the pupil and ptosis or pseudo-ptosis were present, these apparently being caused by injury or section of communicating branches to the sympathetic. The case of thoracic "cyst" was distinctly in its appearance like those which have been described as instances of circumscribed serous meningitus. It was localized by hypalgesia, the upper limit of which was two or three inches above the umbilicus. Severe and persisting pain both in the back and in one of the lower extremities, at first without and later with, complete paralysis in both extremities, exaggerated reflexes, including the Babinski response, with bladder and rectal involvement, were the most marked manifestations. After evacuation of the cyst, the pain was for a time relieved, the patient recovered the use of his limbs so that at first coarse movements, and afterwards the movements of the toes, could be performed. He suffered, however, from serious cystitis and delirium, probably dependent upon toxemia. He made what might be termed a partial recovery, but relapsed. In the third case, that of sarcoma of the cauda equina and lumbosacral roots, the early manifestations were pain of an extremely severe character, which affected the back and the extremities, first on one side and then on the other. In this case the anesthesia which developed indicated involvement of the posterior nerve roots, at first of the conus and later of roots higher up, as high as the second lumbar. They were distinctly root areas, not segmental or of the extravertebral neural type. The patient eventually was completely paralyzed, with marked atrophy, paralysis of the sphincters, and the whole train of phenomena showing destructive implication of the nerve roots originating from the lumbosacral spinal cord. The cord itself was also apparently involved by pressure or extensions of the lesion. The differentiation between tumors and cysts, because of the vacillation of symptoms in the latter, is possible only in rare cases. Surgical treatment is advised in all cases like those recorded in the paper: Sometimes for radical treatment, that is, removal of the growths; sometimes for relief, as by emptying the cysts; and sometimes simply for what might be termed "spinal decompression." Effects comparable to those of compression by cranial operations are sometimes brought about by operations upon the spinal column. Instead of optic neuritis, headache, nausea and vomiting, being relieved as in cerebral decompression, the good results are seen in the relief of pains, hyperesthesia, spasticity, etc. Of course spinal decompression must be separated from cutting posterior roots, although both might be of service in the same case.

DISCUSSION.

Dr. William G. Spiller, Philadelphia: The case of circumscribed serous spinal meningitis, reported by Dr. Martin, Dr. Musser and myself, was the first of its kind reported. The patient is now in perfect health except that she occasionally has a little pain in the back, possibly from catching of some fibers. Dr. Weisenburg believes he can distinguish between a circumscribed serous meningitis and a tumor, and presented a case to prove his contention before the last meeting of the Philadelphia Neurological Society. There is no possibility of diagnosing a circumscribed serous meningitis from a tumor. As Oppenheim has pointed out, there will be variation with the fluctuation of the fluid in the dural canal. We cannot have symptoms which will enable us to decide as to whether the condition is one of circumscribed spinal meningitis or tumor.

Dr. George Jacoby, New York: I present two specimens. One was taken from a man who suffered with symptoms of gradually increasing pressure paralysis and paresis and disturbance of sensation for a period of ten or twelve years. He was able to walk to the hospital, but had marked weakness of both lower extremities. There was sufficient sensory disturbance to enable us to make a diagnosis of probable intraspinal tumor at the sixth dorsal vertebra. At operation we found at this sixty dorsal segment an enchondroma growing from the body of the veterbra into the spinal canal, compressing the cord so that the cord was attenuated to simply a filament. The second case was operated on by Willy Meyer and a glioma removed from the cord substance. In this case the entire history of disease was only three months. The first symptoms were weakness of the lower extremities, which progressed so that there was spasticity and paraplegia and all the symptoms of complete pressure paralysis of the cord. The tumor in this case was the size of a large cherrystone. You can easily understand how the difference in location will produce this difference in symptomatology.

Dr. George L. Walton, of Boston: With regard to the level of anesthesia as determining the position of the spinal tumor, one very practical point is to be borne in mind, namely, that the accumulation of fluids, whether in the cord itself or in the membranes, is likely to produce symptoms which may be erroneously credited to the tumor itself. It is true that in the majority of cases the point selected for operation should err in the direction of being set too high rather than too low. But if we always follow this plan, we may be misled, as in a case in which I recently had occasion to advise operation. In this case severe pain in the lower back and extending down the thighs was rapidly replaced by paraplegia, with numbness extending nearly to the umbilicus. Finding it hard to credit the tumor itself with such rapid growth, I was guided rather by the initial pain, and advised removing the tenth and eleventh dorsal laminæ. Operation at this point disclosed the upper limit of the tumor, above which the cord was apparently normal. If the cord had been exposed at the level indicated by the level of anesthesia, its normal appearance would have led to the erroneous conclusion that no tumor existed. I am inclined to credit accumulation of fluid with the rapid extension of symptoms.

DR. JOHN JENKS THOMAS, of Boston: I agree with Dr. Spiller in reference to diagnosing circumscribed serous meningitis from tumor. In regard to the point of differential diagnosis between growths of the spinal cord, whether from the pia or dura, I confess that I have less confidence in our ability to differentiate them exactly. In the case that Dr. Walton referred to I was rather opposed to operation because of the intense character of the symptoms, coming on suddenly, which seemed to him to point to total destruction. Within two or three days the man became completely paralyzed in both sensation and motion.

DR. HUGH T. PATRICK, Chicago: The upward movement of the umbilicus when the patient, lying with his arms folded across his chest, raised his head from the pillow, known as Beevor's sign, is of service in diagnosis in spinal cord tumors. The recti muscles are not paralyzed but the muscles below are paralyzed and the umbilicus makes an excursion of a half inch or even more.

DR. ERNEST JONES, Toronto, Canada: I was Dr. Beevor's assistant for a couple of years and I would add two points to what has been said of Beevor's sign. In some cases you will get it obliquely, not only drawn upwards, as one of the muscles is paralyzed below, but sometimes obliquely to the right or left, which gives a clue to the side of the tumor. Further, in cases of congenital dystrophy with paralysis, the umbilicus is drawn downwards.

DR. M. A. BLISS, of St. Louis: I have had quite a distinct case of circumscribed serous meningitis. A laminectomy was done, then a second laminectomy was done and an endothelioma was found.

DR. C. K. MILLS, of Philadelphia: I am not altogether satisfied with the term "circumscribed serous meningitis" or with the explanation which is involved in the use of this term. In the case which I reported I think it quite possible that there was more than was apparent. Horsley has written on chronic spinal meningitis with cysts, etc., and the probabilities are that there is a universal serous meningitis and possibly chronic meningitis, with perhaps two or three pockets, where cystic foci appear, as in the present case. The differentiation between intrapelvic and spinal tumors can be usually made. We simply have not been careful enough. With the exception of English workers, notably Head, and the earlier works of Dr. Weir Mitchell, and he did many of the things which were pointed out later by Head and his collaborators as early as 1874, the application to diagnosis has not been made.

(To be continued.)

Book Reviews.

Pocket Therapeutics and Dose Book. By MORSE STEWART, JR., B.A., M.D. W. B. Saunders Company. 1910.

This small book contains many facts in concise form. It has been carefully revised and remains a useful source of information on many matters relating to drugs and therapeutics.

New and Non-Official Remedies, 1910. Containing Descriptions of the Articles which have been Accepted by the Council on Pharmacy and Chemistry of the American Medical Association prior to Jan. 1, 1910. Chicago: Press of the American Medical Association. 1910.

This volume is the first of a projected series to be issued annually and to contain a description of the new medicinal substances examined each year by the Council and found to comply with its rules. Acceptance of such substances does not necessarily imply their recommendation. The book should prove a serviceable guide for the practitioner and a useful adjunct to the national Pharmacopeia.

Among School Gardens. By M. LOUISE GREENE, M.Pd., Ph.D. (Yale). New York: Charities Publication Committee. 1910.

The educational possibilities of gardens have been more or less well recognized, perhaps, since the days of Eden. It is only within the past half century, however, that the garden as a means of physical, mental and moral training has become a regular adjunct of schools for children. The present well-prepared volume, representing the results of work done by the author on the Russell Sage Foundation, describes, with admirable concrete illustrations and directions, the nature and purpose of school-gardens and the technic of their establishment and maintenance. The book should prove a useful manual, not only to school-gardeners, but to all amateurs in "agriculture, horticulture and the conduct of rural affairs."

The International Medical Annual. A Year-Book of Treatment and Practitioner's Index. By Various Contributors. Twenty-eighth year. New York: E. B. Treat & Co. 1910.

Presenting as it does a review of the medical literature of the world for the year 1909, this volume consists of a series of valuable articles on comprehensive topics, mostly by English authors. Especially noteworthy and timely are the chapters on seawater injections, on hormones and on bacterial vaccines. There are many admirable plates and other illustrations, and an appendix on sanitary science.

A Textbook of the Practice of Medicine. By JAMES M. ANDERS, M.D., Ph.D., LL.D., Professor of Medicine and Clinical Medicine at the Medico-Chirurgical College, Philadelphia. Ninth edition, thoroughly revised. W. B. Saunders Company. 1909.

The ninth edition of this well-known volume on the practice of medicine has been amplified somewhat to meet the demands of changing and increasing knowledge. The section on the nervous system, under the general direction of Dr. C. S. Potts, has been very considerably rewritten. In addition to this, certain serum tests and many minor points in the diagnosis of disease have been incorporated. The general appearance and size of the book is essentially as heretofore and it will, no doubt, continue to fill a place of usefulness as a general and necessarily brief textbook of medicine.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JULY 14, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 806 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

MEETING OF THE NATIONAL EDUCATIONAL ASSOCIATION.

THE Meeting of the National Educational Association which was held in Boston last week, although having only an indirect relation to medicine, is still important from a medical standpoint as indicating certain definite tendencies of recent investigation.

It may, with justice, be said that the main effort of research in the past few years has been toward the prevention of disease in a large way. We hear much talk of preventive medicine as contrasted with the somewhat futile attempts toward the treatment of individual conditions. This well-marked tendency has unquestionably brought the medical profession into close relations with various other and apparently unrelated departments of investigation and nowhere could this be more strikingly shown than in some of the papers presented at the large meeting to which we have referred.

In the child study department the joint meeting was held with the elementary departments at which the main subject for consideratian was the "special child." Not many years ago the "special" child would have had small consideration at such a gathering but such has been the progress in practical psychology that the type of mental development offered by the unusual child provides a source of most interesting and profitable discussion. Dr. Grossmann of Plainfield, N. J., drew attention to the development of so-called nervous symptoms in childhood, pointing out the very great importance of recognizing the character of such symptoms and of directing the education of the child accordingly. He even went so far as to say that " no man or woman should be considered fit to marry who cannot give evidence of training in parental functions." Whether or not this Eutopian state will ever be reached it is not our present purpose to discuss but the fact is certainly being borne in upon physicians as never before that many of the nervous ills of later life are directly traceable to a misinterpretation of certain signs and conditions in childhood. What is called the exceptional child is not infrequently merely the result of defective methods of training and it is not to be questioned that the prophylaxis of certain neuroses in the future will lie largely in the recognition of their development in the child. That these matters, which are becoming increasingly apparent to physicians, should have a free discussion at a general educational meeting is a matter for congratulation and undoubtedly indicates a more comprehensive grasp in the future of the entire intricate subject.

Dr. Goodhart spoke of the so-called nervous child and bore out in great measure what Dr. Grossmann had said. He maintained that the atypical class has by no means received the attention which its importance to society warrants. Such children are a valuable intellectual asset but manifestly they cannot be classified with average children and demand individual instruction and close personal study. All this is a certain reaction against the too popular theories of late so much in vogue, that the regeneration of the world must consist in the elimination of those persons commonly called the unfit. The subject must be looked at from a broad standpoint and both what the world gains and what it loses by the existence of such unusual persons must be most carefully considered before any far-reaching theories are promulgated. In any event the present tendency to regard the unusual or atypical child as worthy of profound study is a step in advance which should be most widely recognized and encouraged.

Matters relating to school hygiene also brought certain meetings of the Associatian in close relation with medical progress. Dr. R. C. Cabot read a highly suggestive paper on " The Deeper Significance of the School Hygiene Movement " in which with his usual directness he pointed out certain definite defects in our present methods. He deprecated permitting hygiene to become a master rather than a servant and also the somewhat common tendency to be " acutely conscious of one's physical health." An excellent bit of philosophic medicine was condensed into the following statement " One should not be thinking of his body or of his soul. He should be thinking of his job and of his God." Dr. G. Stanley Hall

of Clark University spoke on "The Psychological Aspect of Physical Education" and pointed the way to a proper conception of the significance of athletics. There were many other papers of similar interest to physicians. Although medicine is not directly represented in the numerous sections of the society it is apparent that such educational bodies can no longer afford to ignore its contributions to the great problem of secondary education.

PUBLIC ENLIGHTENMENT ON MEDICAL SUBJECTS.

In *Harper's Magazine* for July, 1910, is an article by a well-known surgeon of Philadelphia entitled "The New Surgery." Briefly, yet clearly and without technicalities, he outlines the newer operations and the reasons for their performance. Such articles as this supply the same information although to a different audience, as do the public lectures such, for example, as have been given on Saturday evenings and Sunday afternoons at the Harvard Medical School and elsewhere. As a result of these, and of the reports concerning milk inspections, pure food legislation, the fight against tuberculosis, and other matters of public health, the people are gathering, first and last, a considerable store of hygienic and medical knowledge. Mysticism in medicine is fast losing ground; the people want to be "shown."

To hold the confidence of the public, medical men must supply accurate information as it is demanded. While it remains a very open question as to how much the laity should be instructed in matters which at best they can only partially understand, there is a growing feeling that they can be made to appreciate essentials and that their better understanding of medical situations will benefit both patient and physician.

As people acquire more and better knowledge of general medical facts, they will try the "family remedies" less rather than more. Many a case of appendicitis will be saved a long period of drainage when the mothers cease to give castor oil before calling a doctor. In hospitals operations can be better performed, and better nursing obtained than in the home, yet the fear of the hospital, due to the idea that people are taken there, only to die, is still an obstruction, though a fading one to the best practise. Consent to operation or other therapeutic measure can often be obtained quickest by a simple statement of the nature of the disease and the purpose of interference.

EXTERMINATION OF MOSQUITOES ON STATEN ISLAND

The warfare which Dr. Doty, health officer of the port of New York, has been waging against the mosquito on Staten Island for the past ten years has at last been crowned with almost complete success. At the time when he set about this undertaking it was common knowledge that nowhere along the coast was the mosquito situation worse than there. After a long series of experiments he was able to prove that the striped-legged variety, which comprised 90% of the whole number of mosquitoes, is a salt-water insect and bred only in the marshes along the shore, and that the brown-legged, or malaria-producing variety is bred only in inland waters, and cannot live in salt water. The problem then was to make these marshes uninhabitable by the pests, and with that object in view the systematic drainage of the marshes was undertaken. Dr. Doty now reports that these marshes have finally been turned into hard ground, with the ditches, about ten inches wide and two feet deep, in perfect working order, and the result has been the practical extermination of the salt-water mosquito. Moreover, he has been informed by a number of professors of the agricultural department of Cornell University, whom he asked to make an inspection of the reclaimed marshes, with a view to ascertaining their agricultural possibilities, that within a short period they will make fine farm lands, which could be made to yield several crops a year. In the meanwhile, systematic efforts have also been made to exterminate the brown-legged variety, and Dr. Doty hopes soon to see this accomplished also. As a result of this work, malarial fever, which was formerly very prevalent on the island, has been gradually diminishing, and at present is a comparatively rare affection.

MEDICAL NOTES.

PLAGUE IN HAWAII. — On July 6, 1910 occurred the first death from bubonic plague in three years. There have been several cases of plague during the past few months, but only one case resulted fatally.

A CENTENARIAN. — Ignatius Neggersmith, the first and oldest jeweler in the Borough of the Bronx, died on July 6, in his one hundred and second year, having celebrated his one hundred and first birthday in March last. He was born in Westphalia, Germany, and came to this country sixty-four years ago. He is survived by two sons and two daughters, and the eldest son

is seventy years old. He leaves also thirty-seven grandchildren, twenty-seven great-grand-children and four great-great-grandchildren.

A New Cause of Accidents. — The recent accident to Baroness Delaroche while driving an aëroplane at Rheims, points to another and rapidly increasing cause of injury or death. While 150 feet above ground, Baroness Delaroche lost her presence of mind when another machine whizzed over her, and, cutting the ignition wire to her motor, she caused her aëroplane to lose momentum and plunge to the ground. Laws are needed, and will doubtless soon be passed, prohibiting such interference between flying-machines.

The Importance of Malaria. — Among the problems which the South must settle, not the least is that due to malaria. The number of deaths from this disease in 1900 was 14,909, its annual cost to the nation from eighty to a hundred million dollars. In certain localities it causes one quarter of the deaths. The prevalence and economic significance of the infection was described by Dr. Searle Harris of Mobile, Ala., at the sixty-first annual meeting of the American Medical Association. He believes that malaria can be eradicated in one year in any community if the increase of the infection-bearing mosquitoes is limited, and if every person having the disease will take enough quinine.

Changes in the Personnel of the Medical Faculty at the University of Pennsylvania. — The trustees of the University of Pennsylvania have announced recently certain changes in the personnel of the teaching staff to go into effect at the beginning of the next academic session, Sept. 1, 1910.

To fill the Chair of Theory and Practice of Medicine made vacant by the resignation of Dr. James Tyson, Dr. David L. Edsall has been transferred from the Chair of Pharmacology and Therapeutics and the vacancy in the latter will be filled by the appointment of Dr. A. N. Richards, now Professor of Pharmacology in the Medical School of the Northwestern University.

One hundred thousand dollars has been received for the endowment of a Chair of Physiological Chemistry and Dr. Alonzo Englebert Taylor of the University of California will be its first occupant.

Dr. Richard M. Pearce of the University and Bellevue Hospital Medical College of New York, has been appointed Professor of Pathology. Dr. Pearce will also direct the work of the Department of Research Medicine recently established by an endowment of $200,000.

Dr. Allen J. Smith, the present Dean of the Medical School will be the occupant of the new Chair of Comparative Pathology and be at the head of the newly instituted courses in Tropical Medicine.

Dr. Paul Lewis, who will have charge of the laboratory of the Phipps Institute for the Study, Prevention and Treatment of Tuberculosis, now an integral part of the University, has been elected Assistant Professor of Pathology.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston.— For the week ending at noon, July 13, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 32, scarlatina 17, typhoid fever 7, measles 84, smallpox 0, tuberculosis 93.

The death-rate of the reported deaths for the week ending July 13, 1910, was 20.20.

Boston Mortality Statistics. —The total number of deaths reported to the Board of Health for the week ending Saturday, noon, July 9, 1910, was 220, against 180 the corresponding week of last year, showing an increase of 40 deaths and making the death-rate for the week 18.21. Of this number 115 were males and 105 were females; 215 were white and 5 colored; 143 were born in the United States, 72 in foreign countries and 5 unknown; 39 were of American parentage, 158 of foreign parentage and 23 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 45 cases and 4 death; scarlatina, 16 cases and 2 deaths; typhoid fever, 5 cases and 2 deaths; measles, 98 cases and 2 deaths; tuberculosis, 65 cases and 20 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 23, whooping cough 1, heart disease 19, bronchitis 3. There were 17 deaths from violent causes. The number of children who died under one year was 47; the number under five years, 71. The number of persons who died over sixty years of age was 41. The deaths in public institutions were 99.

Cerebrospinal meningitis, 1 case and 2 deaths.

Of the above infectious diseases the following were non-residents: Consumption, 1 case. Cerebrospinal meningitis, 1 case and 1 death.

Deducting deaths of non-residents, the total is 193 and the death-rate is then 15.98.

WORK OF THE FLOATING HOSPITAL.— The exceptionally hot weather of the past week has been partially mitigated for those admitted to the Floating Hospital. On Sunday, July 10th, the hottest day of the year up to that date, 183 mothers and children were on board. The following day, when the thermometer reached a still higher point, 234 were accommodated on the boat. New permanent patients are continually being added to those under treatment.

THE WALCOTT FELLOWSHIP.— It is announced that Dr. F. C. Shattuck, Jackson Professor of Clinical Medicine at the Harvard Medical School has offered a fellowship to the University to be called the Henry P. Walcott Fellowship in Clinical Medicine and that this offer has been accepted by the President and Fellows. Dr. Shattuck's offer was made in the following words: "It is my desire to testify to my grateful appreciation of what medicine has done for my family and for me, to my love for the profession, to my hope for its future, to my admiration for a dear friend who has greatly adorned it. I therefore wish to bind myself and my estate in the sum of twenty-five thousand dollars, when and as paid to become part of the general funds of the University and to receive its share of the income thereof.

"The income of this fund is to provide for the support of a Fellow in Clinical Medicine, who shall receive his appointment from the Corporation on nomination by the Jackson Professor of Clinical Medicine, who, while the holder of the Fellowship, shall not engage in private practise but devote his time to teaching and clinical research work. It is my hope that the hospital within which his work is done may give him some sort of residential position.

"It is my wish that the Fellowship be called 'The Henry P. Walcott Fellowship in Clinical Medicine,' in evidence of my affection and regard for Dr. Walcott, whose great abilities, rare wisdom and human sympathies have for so many years been unselfishly devoted to the University, state, and mankind, in many and varied directions.

"As soon as such Fellow is appointed, I will engage myself to see that he receive not less than one thousand dollars per annum up to such time as the payment of the full twenty-five thousand dollars is completed."

NEW YORK.

RETIREMENT OF DR. BURT G. WILDER. — Dr. Burt G. Wilder, Professor of Neurology and Vertebrate Zoölogy, is one of three Cornell professors who have just been retired on Carnegie pensions. Professor Wilder, who was a pupil and assistant of Agassiz, joined the Cornell Faculty in 1867, the year instruction was begun in the institution, and has served continuously since that time.

A REMARKABLE OLD MAN. — Brooklyn has a remarkable old man, one, Solomon Levy, who claims to be one hundred and six years old. He recently distinguished himself by falling from the roof of his two-story house without breaking any bones or apparently receiving any other serious injury. When admitted to the Jewish Hospital he was suffering from shock, and, from his extreme age, it was expected that he would certainly succumb, but two weeks' treatment completely set him up; so that when he was discharged at the end of that time he was able to walk some distance unaided to take a trolley car to his home.

5. Morley, J. *Case of Papilloma Causing Hydronephrosis in a Horse-shoe Kidney.*
6. Middleton, G. S. *Rat-bite Fever.*

1. Morris gives various illustrative cases of pyonephrosis and concludes as follows: (*a*) Pyonephrosis should be drained through a lumbar incision as soon as the diagnosis is established; (*b*) in many-chambered pyonephrosis it is very important to see that all the chambers are opened and drained; (*c*) it is useless to try to drain a suppurating kidney through an incision in front; (*d*) in advanced cases nephrectomy is often the only cure.

4. Gray presents his last series of 100 cases of spinal anesthesia in children with comments as to technic and management; he uses 3% eucaine for preliminary anesthesia of the skin and punctures in the second or third lumbar space; the child should be immediately turned over and the pelvis raised for fifteen or twenty seconds. The level of the paralysis is regulated by the bulk of the fluid raised — i. e. the larger the bulk of fluid the higher will be the resulting anesthesia; the duration is influenced by the amount of stovaine used. This procedure involves far less surgical shock, little or no vomiting, much less pain and a great diminution in danger of pneumonia or bronchitis. [J. B. H.]

3. Doyne, R. W. *Observations on Conjunctivitis.*
4. *Batten, F. E. *Influenzal Meningitis.*
5. Verdon, W. *A Comparison Made Between the Simple Gastro-Circulatory Seizure and the Angina Pectoris Attack.*
6. Stevens, B. C. *Four Cases of Sporadic Cretinism in one Family.*
7. Barnes, J. A. *A Note on the Treatment of the Partially Drowned.*

4. Batten reports 5 cases of influenzal meningitis with a few general remarks as to the previously reported cases and the history, symptomatology, diagnosis, and treatment of the rare condition. The first case was reported in 1892; Cohoe has collected 26 cases of this condition of which 50% occurred in children under one year with a fatal termination in every case. Accurate diagnosis is only made by a recognition of the organism. As to treatment, lumbar puncture does not seem to be of great value. The administration of urotropin seems to be of benefit. [J. B. H.]

9. Runeberg, J. W. *Pottenger's Light Touch Palpation.*
10. Meyer, R. *Is there Transmission of Acquired Properties?*

3. Schumburg in carrying further some previous experiments concludes that it is perfectly safe to wash one's hands in absolute or denatured alcohol with a view to sterilizing them without previously scrubbing them with soap and water. This is of great practical value for surgeons on the battlefield.

4. Hersog reviews some of the methods of treating

severe anemias by means of blood injections. Some authors have reported the injection subcutaneously of defibrinated blood and some of blood not defibrinated. In his work he has used about 20 ccm. of defibrinated blood and injected it into the gluteal region. He explains his technic and goes into a discussion of the theories by which it might have some effect. He has tried it on five cases and although he admits that there are too few for conclusions he reports distinctly favorable results and calls for a wider application of the method. [C. F., JR.]

1. By means of an instrument of his own the writer studied the intravenous pressure in the median vein. He found the normal pressure at this point to be about 70–80 mm. of water. In compensated valvular diseases of the heart (with few exceptions) the venous pressure was normal, but in cardiac insufficiency pressures of over 200 mm. were recorded. With edema of the lungs increased venous pressure was repeatedly observed and high venous pressure was regarded as a warning of this danger. Venous pressure is reducible by diminishing the amount of blood in the veins or by increasing the output of the left ventricle; that is by venesection, by cardiac stimulation or by a combination of these. To reduce a high venous pressure nearly to normal by phlebotomy nearly a pint of blood had to be withdrawn. Similar results were obtained by entrapping the circulating blood in the limbs by means of rubber bandages put on in such a way that the veins of the limbs became full of blood. This method gave good results when actual bleeding was contra-indicated. Its chief disadvantage was the danger incurred if the bandages were suddenly removed. (This danger can be obviated.) In pneumonia, cardiac insufficiency with high venous pressure was observed and treated in the same way, but the writer emphasizes the fact that in pneumonia circulatory weakness is generally due to vascular dilatation, and that is such cases, the venous and arterial pressure are both abnormally low. This condition demands vasoconstriction.

2. The writer draws important conclusions for his work with streptococci. He says that virulent streptococci generally have the power of causing hemolysis, that this power is acquired by infection and lost when the streptococci grow in contact with the bodily secretions or on the skin, that the human is the carrier of the streptococcus and that these bacteria are numerous in the vicinity of infected persons. 3. Regarding the rôle of the streptococcus to be the important factor in the severity of an attack of scarlet fever these authors have been using both serum and vaccine in the treatment of their cases. They seem satisfied that the best results so far obtained have been from a combined use of these two agents. The fact that nephritis, one of the commonest sequelæ of scarlet fever, does not seem to be found in cases treated with this combination seems more than a coincidence. They report their observations on a series of 52 cases. [J. L. H.]

7. An interesting series of cases is here noted. The patient in question is an active business man of fifty-four years. His grandmother was "blue" from birth until she died of old age in her seventy-sixth year. His mother also was cyanotic her entire life. She enjoyed moderately good health and died in her forty-eighth year. The patient himself has always been very well and active. Though a slight heart lesion was detected at the time of his examination for the German army it was not considered sufficient to relieve him from service and he stood his two years of enlistment perfectly. His sister and her child as well as two of his children have the same cyanotic appearance without any apparent ill effects. [J. L. H.]

3. HALLERVORDEN, J. *The Use of Pantopon (Sahli).*

1. Hirsch discusses at length the subject of arterios clerosis and myocarditis in childhood and adolescence. Func-

tional changes, not luetic or secondary to nephritis, may well be present, though not demonstrable, in the arterial walls as early in life as this. Children suffering from palpitation and precardial distress often have no sign of cardiac hypertrophy except palpable arteries and prolonged pulse. In such cases of "juvenile sclerosis" there is thickening of the media not of sclerotic nature.

Irregularity of the pulse without demonstrable heart lesion is fairly common in childhood. Arrhythmia may occur after poisoning with digitalis or opium; after hard vomiting or other severe digestive disturbance; during convalescence from infectious diseases; in anemic and nervous children and in children harboring intestinal parasites. There is such a thing as physiological arrhythmia in childhood, a phenomenon sometimes observed during sleep. These functional arrhythmias of childhood are produced in a characteristic way. The separate pulse beats are equal in force and volume, but diastole varies in length. The irregularity disappears with accelerated heart action, because abnormally long diastoles are thereby shortened. Arrhythmia from organic disease of the heart muscle is as a rule very different in character, being due to extra systolic contractions.

In childhood harmless heart murmurs are relatively very common. Beyer found systolic murmurs in 42% of 830 school children examined; they were more numerous among the girls. Lüthje found 623 systolic murmurs in 854 children. Of these 623, 564 were heard only over the pulmonary area; only 2% had certain valvular insufficiency. These functional murmurs cannot be wholly explained. The writer thinks that many times they are due to mitral regurgitation from temporary muscular insufficiency. [L. D. C.]

10. LÄWEN, A. *A Thoracic Deformity in Long-Existent Artificial Anus in Childhood.*

4. After brief review of other procedures for insuring asepsis in the performance of intestinal anastomosis, Martini describes a device of his own, a metallic clamp, called an enterotribe, by means of which he secures together the two viscera to be anastomosed. This clamp is then buried by a circular serous suture, and after a few days sloughs through into the lumen of the intestine, establishing the anastomosis, and is recovered in the stools. The author has excellent results in experimental operations performed on dogs by this method, for which he claims the advantages of quick and easy technic, avoidance of infection from intestinal contents, and opening of anastomosis only after formation of abundant adhesions to prevent leakage.

7. Zesas considers the subject of status lymphaticus and thymus death in its relation to surgery, and collects from the literature 21 cases of persistent or hypertrophied thymus treated by operation. He believes this condition is of the greatest importance, is capable of early diagnosis and has a relatively good prognosis under prompt surgical intervention. [R. M. G.]

3. *ALMAGIÀ, M., AND TATA, R. *Researches on the Defensive Action of Stasis.*
4. STEFANO, P.-A. *Congenital Cystic Lymphangioma of the Neck.* (To be continued.)

1. Serafini reports three cases of lipoma of the pericranium and two of lipoma of the sole of the foot. (Among unusual situations of lipoma these seem hardly so uncommon as the pericardium.)

2. From an extensive microscopic study of specimens from six cases, Gaudiani concludes that the greater part of the cutaneous tumors described under the title of endothelioma are in reality epithelial tumors, having origin in the corium, not by direct proliferation of the basal cells of the epidermis but from ectopic epithelial cells having the form of basal cells. He believes that they are distinguished from common cutaneous epitheliomata not only by their structure but by their more benign course, since they do not metastasize and rarely recur after removal.

3. The authors report briefly a piece of experimental research, from which they conclude that the hyperemia of stasis hinders the absorption of toxic substances and is in so far a defensive agent. [R. M. G.]

3. PERGOLA, M. *The Isolation of the Spirillum of Asiatic Cholera.*
4. MAGGIORE, S. *The Influence of Various Aggressins on Experimental Infections with Micrococcus Melitensis.*

2. La Franca and Campese produced experimental pneumothorax in dogs in order to study the respiratory mechanism. They conclude that in unilateral closed pneumothorax it is not modified except that the respiration is less deep on the affected side. In open pneumothorax there is always marked dyspnea characterized by rapid respiration, dilatation of the thorax, inequality of the respiratory excursion, and (less frequently) deep respiration on the affected side. In valvular pneumothorax the respiratory rhythm is more or less like that in closed pneumothorax.

These experiments lead the writers to believe that the reflex dyspnea of open pneumothorax is not due to the presence of air in the pleural cavity or to its rapid filling with air. It is due either (1) to the free escape of air from the cavity at each expiration and the want of normal elastic resistance to the same, or (2) to some abnormal muscular sensation. The second explanation is supported by the writers' observations that anesthesia of the pleural nerve endings does not inhibit the reflex. [L. D. C.]

Obituary.

H. H. A. BEACH, M.D.

DR. H. H. A. BEACH, long a prominent figure in Boston medicine, died June 28, at the age of sixty-six years. Dr. Beach was born in Middletown, Conn., Dec. 18, 1843, but during his childhood the family moved to Cambridge, Mass., where his preliminary education was secured. At the age of twenty he enlisted in the regular army and was given the post of Sergeant of Ordnance in

the hospital service. He served in this capacity until after the close of the Civil War when he was honorably discharged and accepted the position of surgical house pupil at the Massachusetts General Hospital. He was graduated from the Harvard Medical School in 1868.

After leaving the Massachusetts General Hospital he at once began the practice of medicine in this city. He was appointed a surgeon at the Boston Dispensary and an assistant demonstrator of anatomy at the Harvard Medical School. He later became demonstrator in the same institution and a member of the faculty. For fifteen years he taught anatomy in connection with the lectures of Oliver Wendell Holmes, then professor of anatomy. Later his teaching became more clinical in character and he was for many years an instructor in the department of clinical surgery. This came about naturally through his connection for nearly thirty years with the Massachusetts General Hospital as one of its surgeons. At one time Dr. Beach was an assistant editor of the BOSTON MEDICAL AND SURGICAL JOURNAL. He held membership in various medical societies both state and national and contributed many articles to medical journals.

In 1871 Dr. Beach married Miss Alice Mandell, of New Bedford, Mass., who died in 1880. Five years later he married Miss Amy N. Cheney, of New Hampshire, whose highly cultivated taste for music found a ready sympathizer in her husband.

In the death of Dr. Beach, Boston loses a surgeon long associated with its best traditions. For many years he combined hospital work with a very extensive private practice which was both exacting and time-absorbing. Although his activities had been somewhat modified during the past few years he was still active preceding his final illness which was a short one. Dr. Beach had, through the age limit, been retired as a visiting surgeon from the Massachusetts Hospital for several years, but he still retained his interest in the institution which he continued to serve in a less exacting capacity as consulting surgeon.

Correspondence.

PARIS LETTER.

THE EFFECT OF RADIUM ON CANCEROUS TUMORS.

[From our Special Correspondent.]

PARIS, JUNE 26, 1910.

Mr. Editor: One of my early recollections in clinical surgery is that of Verneuil passing through his huge wards at the Pétié with a crowd of students, and after examining case upon case of cancer of various sorts, raising his arms in the air with a gesture of despair and exclaiming: "*Ah, Messieurs,—toujours le cancer; partout le cancer!*"

My impression then was that a large portion of humanity must succumb to this dread disease, and that sooner or later it would overtake me with the rest of mankind. I afterwards found out that very fortunately the aspect of a large surgical clinic in a center like Paris does not reflect the conditions of general practice by any manner of means, and that cancer, while still only too frequent and fatal, is far from being as common as the state of affairs in Verneuil's wards led me to believe.

The treatment of cancer has been up for discussion at some length in Paris during the past month.

The indefatigable Doyen gave a course of six lectures on his "mycolysine" methods, in which he reaffirmed his former assertions as to zymotic diseases and their speedy disappearance under the influence of this substance and proceeded next, to tell his audience that the great majority of tubercular patients of the first and even of the second stage got well with it likewise; and finally ended with a lecture on his electro-coagulation method for cancer, in which he states that under the action of this caustic serious cancers of the tongue, pharynx and intestine had been cured in a single sitting, and had not recurred in the eighteen months that have elapsed since treatment!

No one would be more delighted to believe all this than myself; but I am really surprised that Doyen does not realize how heavily the chances are against him. He offers us *too* much at once! Any one of the three results he announces would suffice to raise him to a pinnacle that would satisfy the most ambitious of mortals; but the three together! Nor do I think that Doyen would be altogether flattered if he could hear the appreciations of his French colleagues as to his veracity in scientific matters.

He closed by saying that surgery must rapidly change its ways, in cancer. In the future the knife must only be a means of exploration, "for it cannot heal and often infects"!

Now just about the same time as Doyen was bewildering his "*mondain*" audience with his discoveries, which somehow or other never seem to get beyond the walls of the clinic in the rue Piccini, the Paris Society of Surgery, of which he is not a member, had before it for discussion the treatment of cancer by radium, and, incidentally, the various other means of treatment were brought into the debate. Now two facts stand out prominently in the reports of these two sittings as published in the society's official bulletins: one is that no tumor should be treated by radium alone, so long as it is in a proper stage for surgical removal first; the other is that Doyen's electro-coagulation method was not even mentioned! This does not look as though the results of his latest discovery are quite as overwhelmingly demonstrative as he would have us believe.

The radium discussion was about as exhaustive a one as I remember to have seen take place before the Society of Surgery, a large proportion of the prominent surgeons of Paris reporting the results of their personal experience in the matter. In this instance, as was the case with their news on the late regretted fulguration method, opinions in this learned body were singularly unanimous. There were minor differences in some details, but the general consensus was, I think, the following: nothing that can be called *cures*, in the serious forms of cancer, but striking and most interesting results in many cases, amounting to what might be called complete remissions or cures *pro tem.*

In view of the practical interest of this discussion, and of the authority of the opinions emitted, it may be of service to cite the speakers personally and in order.

The origin of the discussion was a paper presented by Wickham and Degrais, in which they laid stress on three points: That radium should not be used indiscriminately; that in the majority of cases it should be combined with surgical intervention; that the results obtained, though often favorable, are never more than local, and that there is a long way from the regression of a tumor to the definite recovery of the patient from his disease.

The different artifices used by the radium-men are probably well-known to your readers: The crossed-fire, whereby a maximum of rays are brought to bear on a given region; the filtration, whereby the effective, gamma-rays are separated from the alpha and beta rays, were detrimental to the superficial tissues; the spreading out of radium salts onto broad plasters for application; and the introduction of radium salts in tubes into the substance of tumors themselves, singly or in numbers. All this is more of the domain of the specialist.

Professor Segond, the first to speak, began by resuming his experience in the following words: "In no case have I seen radium cure a neoplasm. But on the other hand I have observed it gives rise to such changes in the evolution of malignant tumors, result in such curious transformations,

produce, in short, in certain cases such important improvements, that in all cases in which the disease is not, or is no longer, justifiable of surgical intervention, I think that for the time being radium is indicated."

Segond's experience is particularly interesting as regards cancer of the tongue, of which he reported five cases with most satisfactory results. Thus, to cite one of these cases: Cancer of the floor of the mouth, very extensive, the patient's condition being lamentable in the extreme, a single application of radium, pure radium sulphate in two tubes, produced a remarkable improvement. The ulceration healed up, and the patient was once more able to speak and swallow.

The results in his other four cases were equally striking, and he remarks: "With all of these patients there was manifestly no definite recovery; but these men, who suffered with violent pains, had extensive ulcerations which bled and emitted an offensive discharge, and whose cancers were rapidly progressing, found that with one or two applications of the radium tubes, the hemorrhage and discharge ceased, the ulcerations healed, the infiltrated region became more supple, pain diminished, and life became bearable at least for a certain time."

With uterine cancer, however, Segond's experience has not been as promising as some of his colleagues, and his opinion is that with tumors of this region there is peculiar liability to deep and treacherous extension beyond a cervix that is healed to external appearances.

Delbet, though reserving his detailed opinion on the question for the international Cancer Congress to be held in Paris next October, said that the enormous advantage in the radium treatment consists in the fact that you can put it just where you wish it to go. He either places his tubes in the fungous tissue itself (rectum, uterus), or he plunges them into the tumor substance with the help of an ordinary trochar. He does no ray-filtering, but takes advantage of the entire, composite emanation; with his method there are no superficial tissues to be spared, the tubes being in the tumor themselves.

He has found that the area about the tube that is affected by the rays is not more than two and a half ccm. deep, and even in this zone the cancer cells are not equally influenced; there is a first zone where the cells are destroyed; a second where they may either be destroyed or else have their evolution modified; and a third where they show signs of stimulation! The way to get around this short range and uneven action of the rays is to spit the tumor with tubes, particularly at its circumference, so that their action will extend beyond its limits, which is not always easy to accomplish. His view is that radium is in the nature of a caustic, but a caustic improved, refined and infinitely superior to other caustics.

In cancer of the uterus his experience has been diametrically opposed to that of Segond; he has found that cervical cancer, and in general pavement cancer, particularly in its mucous form, is peculiarly sensitive to the action of radium.

Tuffier claims to have shown that the action of radium is an elective one for the cancerous cell, the connective frame-work being respected, its nutrition modified without destruction of tissue. He thinks that the action of x-rays is identical with this, as opposed to high-frequency and thermotherapy, in which there is total destruction of tissue.

After citing several interesting cases of cancers apparently hopeless having been so much improved as to enable an operation to be carried out under fairly favorable conditions, he was the first to speak of cases in which the patient's condition had been unquestionably aggravated by the treatment. One was that of a cancer of the lip, treated with radium, with recurrence after eight months. "Never do I remember to have seen a cancer of the lip have an evolution so rapidly fatal."

In uterine cancer the local result is often remarkable, and Dominici has laid stress on the fact that it is precisely on these large fungous masses that radium has the greatest influence; but it is not possible to infer from this improvement that the case is cured, as the healed scar is simply a mask, back of which the trouble pursues its evolution in the depths. Tuffier concluded his remarks as follows: "In short, if I were asked to sum up my opinion on radium I would say that I do not know of a single case of mucous or deep cancer that has been cured, but that I have seen very remarkable local improvements which justifies its use when surgical intervention is impossible. It is certainly the best palliative that we now have at our disposal."

In Lucas-Championnière's opinion the action of radium in cancer is unquestionable, and in many cases renders the most signal service. In the case of a woman of thirty-six, with a cancer of the recto-vaginal wall, a large tumor making rapid progress, ulcerated and with profuse and fetid secretion, he and Segond considered the neoplasm beyond the limits of operative intervention, an operation requiring removal of the vagina, rectum and uterus, and the establishment of an artificial anus. Radium treatment with this woman produced such an astonishing improvement in the local and general conditions that her friends could not believe their senses when they saw her up and about and resuming her usual occupations.

At the end of seven months there was, however, recurrence, and death took place in fourteen months, — whereas at the time of the consultation between Segond and himself a fatal issue to the case was expected in a very brief delay.

Schwartz summed up his opinion on the matter as follows: radium relieves suffering, prolongs life, and renders operable some tumors that could not otherwise have been touched; but so far as he has seen it has never cured a deep cancer.

Ricard has only had one case, but with a favorable result, an inoperable cancer of the uterus with extension to both *culs-de-sac;* the application of several radium tubes was followed by an extraordinary regression of the tumor, so much so that after the second application the cervix gave the impression of a normal organ with healthy and smooth mucous membrane. The patient thereupon left the hospital, declining hysterectomy which he had proposed.

Nélaton has also had a case of cervical cancer favorably influenced by radium, the result being that he, Dominici and Champetier de Ribes, all look on the case as cured! They are the only ones who used that term.

Lejar's experience has been fairly extensive, twelve cases, nine of them uterine cancers. Five of the latter were not modified by the treatment, beyond slight amelioration of symptoms. He thinks that certain forms of uterine cancer are absolutely refractory to this agent, and that unless improvement shows itself after one or two applications it is useless to persevere. In the four other cases, however, the results were very striking, amounting fully to temporary recovery, in spite of the fact that with one of the women the vagina was filled with a vegetating, friable, bleeding mass the size of a fetus-head!

Morestin, while confirming the opinions of the speakers who had preceded him as to the remarkable palliative results of the treatment but the uncertainty as to the ultimate outcome, laid stress on the fact that these temporary results lead physicians to try radium from the start, while the tumor is still operable, and thus lose precious time that subsequently cannot be regained. He was also under the impression that in some cases there is distinct aggravation.

Sieur has likewise had a case in which the evolution appeared to be unquestionably hastened by the radium treatment.

Tuffier spoke a second time and queried whether in certain instances cancer-generalization is not to be laid to the door of the radium treatment.

Walther, in turn remarked that radium applications, though producing rapid cicatrization and apparent recovery, give rise to proliferation of the epithelium in the deeper tissues, and cited a case in point.

Rontier has had two cases, with unfavorable results. Quena has not tried the method. Guinard emphasized the opinion of the majority of the society's members, that so long as a tumor can be removed by the knife, no valuable time should be wasted in radium treatment. Monod then closed the discussion.

It is, as I remarked in the beginning, not every day that a question is taken up by the Society of Surgery with this throughness, and it is of the highest interest to hear the news of these distinguished men on this method. Some of the cases related *in extenso* are really quite remarkable, almost incredible, were their authority not so reliable. So that in spite of the generally discouraging ultimate results given by the radium emanations we must be truly thankful for these striking palliative successes.

"S."

LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND OTHER OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED JUNE 29, 1910.

IRWIN, FAIRFAX, surgeon. Leave of absence for one month and ten days from Sept. 1, 1910, amended to read one month and ten days from Sept. 15, 1910.

BANKS, CHARLES E., surgeon. Leave of absence for twelve days from June 12, 1910, amended to read ten days from June 15, 1910.

WASDIN, EUGENE, surgeon. Granted one month's leave of absence from June 22, 1910, on account of sickness.

BROOKS, S. D., surgeon. Detailed to represent the Service at the meeting of the American Institute of Homeopathy to be held in Los Angeles, California, July 11–15, 1910. June 25, 1910.

COBB, J. O., surgeon. Granted seven days' leave of absence from June 26, 1910.

GEDDINGS, H. D., surgeon. Detailed to attend the First International Congress of Administrative Sciences to be held at Brussels, Belgium, July 28–31, 1910. June 27, 1910.

VON EZDORF, R. H., passed assistant surgeon. Granted five days' leave of absence from June 28, 1910, on account of sickness.

LUMSDEN, L. L., passed assistant surgeon. Reassigned for duty in the Hygienic Laboratory effective June 27, 1910. June 24, 1910.

HOLT, JOHN M., passed assistant surgeon. Granted one day's leave of absence from June 19, 1910, and one day's leave of absence, June 26, 1910.

LLOYD, B. J., passed assistant surgeon. Granted one month's leave of absence from June 20, 1910, on account of sickness.

BAHRENBURG, L. P. H., passed assistant surgeon. Granted eighteen days' leave of absence from July 1, 1910.

WARREN, B. S., passed assistant surgeon. Granted two months' leave of absence from July 5, 1910.

STIMSON, A. M., passed assistant surgeon. Reassigned for duty in the Hygienic Laboratory, effective June 29, 1910. June 24, 1910.

SPRATT, R. D., passed assistant surgeon. Granted seven days' leave of absence from June 14, 1910, on account of sickness.

HERRING, R. A., assistant surgeon. Granted fourteen days' leave of absence from July 15, 1910.

ADAMS, F. B., acting assistant surgeon. Granted four days' leave of absence from June 30, 1910.

DUNCAN, W. A., acting assistant surgeon. Granted twenty-eight days' leave of absence with pay and two days' leave of absence without pay from May 5, 1910.

FAHEY, E. W., acting assistant surgeon. Granted seven days' leave of absence from June 24, 1910.

PARKER, THOMAS F., acting assistant surgeon. Granted four months' leave of absence without pay from July 1, 1910.

STANTON, J. G., acting assistant surgeon. Granted four days' leave of absence from June 27, 1910.

WELDON, WILLIAM A., acting assistant surgeon. Granted thirty days' leave of absence from July 5, 1910.

WILSON, J. G., acting assistant surgeon. Granted seven days' leave of absence from June 22, 1910, under paragraph 210, Service Regulations.

SLOUGH, CHARLES, pharmacist. Upon arrival of Pharmacist C. H. Bierman, relieved from duty at Baltimore, Md., and directed to proceed to Pensacola Quarantine, Florida, and report to the acting assistant surgeon in charge for duty and assignment to quarters. June 24, 1910.

GIBSON, FRANK L., pharmacist. Reassigned for duty in the Leprosy Investigation Station, effective April 16, 1910. June 24, 1910.

BIERMAN, C. H., pharmacist. Relieved from duty at Portland, Me., and directed to proceed to Baltimore, Md., and report to the medical officer in command for duty and assignment to quarters. June 24, 1910.

ELDRIDGE, M. B., pharmacist. Relieved from duty at Vineyard Haven, Mass., and directed to proceed to Portland, Me., and report to the medical officer in command for duty and assignment to quarters. June 24, 1910.

APPOINTMENT.

DR. JOHN A. PETERSON, of Hingham, has been nominated by Governor Draper for the position of Medical Examiner for the Fifth Plymouth District to succeed the late J. Winthrop Spooner.

RECENT DEATHS.

DR. ASAHEL NORTON BROCKWAY, of New York died on July 4, from cerebral apoplexy, at Clinton, N. Y., where he had gone to attend the commencement of Hamilton College, of which he was a graduate. He was seventy-four years of age, and was graduated from the College of Physicians and Surgeons, New York, in 1861. During the Civil War he served for a time as assistant surgeon in the army, and he had practised in New York since 1864.

DR. FREDERICK AUGUSTUS LYONS, of New York, died on July 5. He was born in Toronto, Canada, in 1854, and was graduated from the College of Physicians and Surgeons, New York, in 1876, after which he studied in Paris, Berlin and Vienna. He was at various times connected with Bellevue Hospital, the New York Foundling Hospital, and the New York Throat, Nose and Lung Hospital, and from 1885 to the time of his death was surgeon to the New York Fire Department. For several years he was editor of the Hospital Gazette.

Original Articles.

ON THE ETIOLOGY AND TREATMENT OF THE PSYCHONEUROSES.*

BY JAMES J. PUTNAM, M.D.,
Professor of Neurology, Harvard Medical School.

THE subject with which I have undertaken to deal is such a vast one that I can obviously only touch on a few great mountain peaks of a vast country.

The various maladies classified as "psychoneuroses" cause perhaps more misery than any other single group with which the community is afflicted. Not only is this true, but the study of their etiology, their treatment and their prevention, on which you have honored me with an invitation to address you, has an importance far transcending the question of the comfort and happiness of those persons who come to physicians for advice. Without understanding the nature of nervous invalidism in the individual it is impossible to understand the true nature of many traits which count as normal, and of many great social problems which are constantly pressing themselves upon our notice.

There is an additional reason why an intelligent company of physicians should think this subject worthy of being taken up afresh. As matters now stand, some of the graver varieties of these psychoneuroses pass practically untreated, not because physicians fail to recognize them as serious, but because they are thought too serious, too nearly incurable, to be fit subjects for time-absorbing treatment. I have in mind, as examples, two patients, of excellent intelligence and warm affection, who live practically exiled from their homes because they have the obsession that they shall kill some member of their families. I know how hard the successful treatment of such cases is, but I believe that the method of treatment which I shall here mainly advocate holds out good hopes for unfortunate patients of these sorts.

The next point for which I beg your attention is with regard to the therapeutics of these affections. Have we reason to be satisfied with the means of treatment commonly employed? There is a tendency, even among neurologists, to answer this question substantially in the affirmative. It is widely felt that the various familiar measures,—such as seclusion in private and public sanatoriums, engrossing occupation, treatment by hydrotherapy, electricity, hygiene, rest, change, suggestion, persuasion and suitable drugs,—give us, when properly administered, all that we really need to supplement the healing powers of nature. This view I do not share. These modes of treatment are indeed of immense value. They should be cultivated and studied as frequently representing the best means at our command, and the fact should be recognized that when they are used with the confidence, skill and devotion that characterizes the work of the few best men, the results obtained are far better than those which follow their employment in a simply routine fashion. If time allowed I should describe and praise also the team-work of the neurologist and the internist, the surgeon, the orthopedist or the gynecologist. Nevertheless there are some forms of the psychoneuroses that these various measures do not touch and others where their use is often really mischievous because in securing temporary improvements they blind the patient and the doctor to the real diagnosis and the really needed treatment. The justice of this criticism becomes clearer when the question is no longer one of treatment by a neurologist with the aid of some skillful colleague, but of treatment by an orthopedist or a gynecologist or a specialist for the digestion, acting by himself. A good share of the practice of such specialists is among patients with strictly neurological affections. The practical outcome of their treatment is often very good and in many a given case, taken by itself, there is no room for anything but congratulation. But, often, too, patients are treated in these ways, perhaps with temporary or partial gains, who ought to have their illnesses studied on far different lines. The sentiments which one often hears that "neurasthenia is a surgical affection" or that "mental treatment should not be resorted to until other means have failed imply a misconception of the facts." Surgical measures are sometimes of great service and mental measures may be ignorantly used, but it is not an indication of advance in the general comprehension of these disorders that views like these should seriously be held. Good neurology may be rare, but it would be for the benefit of all physicians and of medical theory and practice as a whole if the responsibility and the confidence should be thrown at once where they ought to lie and eventually must lie. So, too, the immense importance attached in some quarters to "eyestrain" as a real cause of fundamental defects of character and of grave psychoneurotic symptoms may be characterized as a truly child-like hypothesis, in view of what we now know to be the facts. I fully appreciate the favorable practical outcome, in some cases, of the eyestrain treatment. But far too much importance has been attached to this argument from therapeutic success in the assignment of real causes. When a patient gets better under a certain treatment it is natural to think that the difficulty which the treatment removed was the essential cause of his illness. But in fact we all know that this is false reasoning and we all know it to be such.

There are two classes of physicians who are very prone, from somewhat contrary reasons, to reach warped judgments in these matters. The first class comprises those who fail to note the relapses from which psychoneurotic patients often suffer who have been relieved by treatments other than the really causal, and so overrate the value of some radically insufficient method. The other class is composed of those who note these

* Read before the Canadian Medical Association, Toronto, June, 1910.

relapses, but observe that they occur under various modes of treatment and then conclude that the relapses belong to the natural history of the disease (a severe form of hysteria or impulsion for example) and that, therefore, the disorder is hereditary and a sign of "degeneration," and that no treatment whatever can be of permanent value. But the former conclusion is a fallacy which any one's observation can correct, and the latter is an unverified assumption which no one has the right to adopt until he has thoroughly acquainted himself with the therapeutic results which can be obtained by the most radical mode of treatment.

The most distinctive feature of neurologic therapeutics has been its effort to utilize mental influences in the cause of health, and I wish to characterize this feature because it is here that important changes for the better are in prospect. You can all recall the stir made by the rehabilitation of hypnotism and what a flood of literature has been published upon "suggestion." You are familiar with the therapeutic work of Dubois and others of his type, and remember also the recent revival of the attempt to find a more scientific bond between medicine and religion.

The great bulk of all this therapeutic endeavor has been an attempt to cure the patient by leading him to dwell on the possibilities of the future and to forget the miseries of the past. He has been urged to "look forward and not back"; to abandon worry as illogical and useless; to see the world at its best; to project his vision beyond the obvious darkness into a region of imagined light. The slogan has been "Do not get discouraged; you can do better if you try," and many a kindly, devoted, ambitious and confident physician has stood ready to play the part of the inspiring leader, the friend toward whom the patient could gaze with veneration and on whom he could lean. In all these efforts there has been much skill and great devotion, but the results have not been wholly satisfactory. Too often the symptoms have been simply quieted for the moment; the disease veneered.

I have outlined the reasons for thinking the study of the psychoneuroses important, the familiar modes of treatment insufficient, and the descriptions of the natural history and course of these disorders often incorrect, because based on an underestimate of what the best treatment can accomplish. Let us now turn to scrutinize the commonly adopted causes.

In the minds of most persons the *hereditary or innate tendencies* take the first place as causes of these psychoneurotic illnesses. It is not remarkable that this is so, when we consider that the signs of nervous weakness in the child—usually taking the form of shyness, timidity, sensitiveness, self-consciousness or of excitability, jealousy and passion — are recognizable so early that they seem to be inborn. Something which prepares the way for these symptoms doubtless *is* inborn, but evidence has been rapidly accumulating of late years which tends to show that experiences after birth are more significant as causes than we have hitherto supposed. The first few years of a child's life are rich in emotions and vague thoughts. These years have never been adequately chronicled, but there are grounds for thinking that traits of character are founded or accentuated at that period which tend strongly to remain through life. In view of those facts, the old phrase "the boy is father of the man" gains a fuller and a richer meaning. A considerable portion of the evidence bearing on this point is associated with the name of Freud, a name to which I shall have frequent occasion to revert. It is obvious also that nervous children have often had nervous parents, and equally so that certain sorts of bodily weaknesses or delicacy which are apparently hereditary predispose to lack of nervous strength. The boy that can play hard and work hard and who comes of sound stock starts life with an obvious advantage, although it may be pointed out at once, as showing how difficult it is to arrive at positive conclusions in these matters, that some of the most striking forms of the psychoneuroses are found among professional and amateur athletes and that seriously nervous patients seem sometimes to have had healthy parents. Finally, common sense seems to demand an acquiescence with the view that the characteristics of the bodies and brains and physiological mechanism with which we are born *must determine* our actions to the strains of life, at least by establishing predispositions of important sorts.

But even though the hereditary or innate influences are fundamentally important as giving a *predisposition* to the psychoneuroses, it is extremely difficult to define with fairness in what this predisposition really consists. The anatomical study of the brains of psychoneurotic patients has thus far taught us nothing. The chemical studies of their excretions have been equally without fruit. We may surmise that if we had the power to make careful physiological tests upon all the nervous functions of the newborn infant we might discover differences in his responses which would foreshadow mental excitability or mental weakness; but the proofs of this are lacking.[1] Towards the close of the last century much evidence was adduced to prove that *physical marks of imperfect local bodily development* (the so-called stigmata) — as lack of facial symmetry, malformation of the ears or eyes—were to be found with such frequency among these patients as to indicate that processes of "degeneration" were silently at work, in psychoneurotic families, tending towards still graver disorders, such as idiocy and sterility, as their final outcome. Even when no obvious physical stigmata were present it was assumed that the nervous systems of such patients might be in some way defective, and many mental pecu-

[1] A very important series of observations bearing on the innate differences in functional vitality between the various mechanisms of the body and their significance for the subsequent evolution of character and temperament has been published by Adler (Alfred Adler: Ueber neurotische Disposition. Jahrb. für Psycho-analyt. u. Psychopath. Forschungen, Bd. 1, p. 526. See also earlier papers by the same author); this work is entirely in line with that of Freud and others of his school, but the principle involved is too important and complex to be discussed in a general summary of this sort.

liarities were enumerated which were supposed to be the outcome of these states. As a portion of this doctrine it was sought to bring every form of eccentricity and even genius into the baleful circle of the degenerative tendencies. But to take such an attitude as this was to assign to stolidity and commonplaceness a position of prominence in a way that mocked at progress, and the credit of the whole scheme suffered severely in consequence. Sterility and idiocy are not characteristic of psychoneurotic families. The creative genius of the artist and the imaginative writer does indeed rest on a similar basis with the symptoms of the psychoneuroses, but neither of these tendencies points necessarily or regularly to " degeneration " as their cause. The main thing to be said in this connection is that there is a real correlation between mental and bodily conditions such as is deserving of careful study. But it is essential that this should be made in a very liberal spirit.

It is true that defects of bodily nutrition are found among these patients which serve both as indications or consequences and also as intensifying causes of their impaired nervous states. The enteroptoses, the dry hair and skin, the impaired digestion, weak muscles, poorly acting hearts and feeble eye-muscles, which are observed so often amongst a certain class of neurasthenics, belong in this category of physical signs. But, important as these conditions are and much as they call for local treatment (which is too well known to need re-statement here), neither their clinical nor their biological significance is clear. Their own etiology is indeed in doubt. They certainly cannot be considered as essential causes of the psychoneurotic illnesses, and on the other hand there is much question whether they are not, to some extent, products rather than antecedents of the disordered nervous and mental states. Disorders of the bodily functions do certainly arise from disordered emotions and may lead in their turn to organic changes on a large scale. Indeed, between the " organic " and the " functional " it is impossible to draw sharp lines. Bodily processes are a sounding-board for mental processes, and *vice versa*. On the whole, the effect of thus seeking to shift the responsibility for these nervous illnesses on to the shoulders of our ancestors has been to make physicians pessimistic as to their power to help toward a cure. The hereditary tendency is conceived of too strongly as " biological " and therefore not to be materially modified in any given individual, and too great emphasis laid upon this point has tended to a gross sort of materialism and fatalism. The belief that a patient's mental sufferings are a reproduction of tendencies which his father or his mother showed before him is too often accepted as an excuse for doing nothing to relieve him. Meantime, another set of facts has been coming more and more prominently forward. The " something " that we inherit is, in most cases, a " tendency " indeed, but nothing more, and—as in the instance of tuberculosis—the actual disease may never show itself provided the patient can be suitably protected against causes operative after birth. So true is this that even where the disease " runs true " through several generations, as in those cases of hysteria or obsessional disorders, for example, where parent and child exhibit the same symptoms, it can often be shown to have been the influence of the ignorant, nervous mother, driven by a fatal impulse to strive toward reproducing herself in her child and the fatalistic impulse of the child to imitate the mother, rather than any real hereditary tendency, that brought the result to pass. This line of thought is so important that we must leave it now only to take it up again.

The *strain of modern living* is the next influence on which stress is often laid, but its consideration need not detain us long. The telephone, the morning paper, the noise of crowded streets, the seething competition and the pressure for a narrow and exclusive individualism such as everywhere makes itself manifest, seem foes of tranquility and health.

But it is probable that these strains appear to be greater than they are and, on the other hand, they bring, in a measure, their own remedies. The pace set is set, after all, by men for men, and while it is too fast for some it is not certain that on the whole it increases faster than the power of adaptation of the majority. At the worst the strains of modern living are mostly obvious and open enemies, whereas the enemies which we have most to fear are those which, in our ignorance, we do not see. If we could but secure all the power of meeting hard conditions that belongs to us by birthright we should not have to strive so hard to make these conditions easier. It is not so much overwork as worry and apprehension that really sap the nervous vigor, and while worry and apprehension doubtless accompany necessary competition and well-founded anxiety and doubt, yet it is a piece of common knowledge that the most harrassing worries are those which are without external provocation but which imply internal tumults of the emotions, the hidden causes of which it now becomes our duty to study at close range.

What are the influences, brought to bear within the lifetime of the individual, that lead to these emotional tumults? How can we best explain the conversion of the emotions into the symptoms of disease? Where shall we best find an adequate treatment? I beg you to take notice of the fact that the actual evolution of our knowledge in respect to these matters has not followed the lines indicated by the questions which I thus ask. On the contrary, the controlling factors in this evolution have been, partly, the scientific tendencies obtaining at the particular periods when the various advances were first made; partly, the qualifications, temperament and training of the particular investigators. It has long been plain to every one that emotional influences were important causes of disease, and various modes of combating these influences have been described, but it is only rather recently

that the origin of these emotions and the mode of production of the symptoms have been measureably understood. The physicians who have been the leading workers in this great field of study may be classified in three groups: (1) The group of the accurate observers, descriptive analysts, natural historians; (2) the group of the therapeutists; (3) the group of the constructive analysts, inductive reasoners, philosophic thinkers. It is possible to describe the symptoms of a disease and to observe many facts in the natural history of its development, as a naturalist studies the characters of an animal or a species, without being greatly drawn to see its real place in the great scheme of nature; it is eminently possible for men of practical instincts — the " nurturing instincts " perhaps they might be called — to treat patients with great success, up to a certain point, without having any adequate conception of the causes of their illnesses.

Consult your own memories and you will see the parts which men of these different types have played. For examples of the *observers and describers* we might go back to Falret and Briquet, who gave us such excellent accounts of *folie de doute* and of hysteria, even in the middle of the last century. The French have always been prominent in these lines, and I will next mention that truly great pioneer in descriptive clinical analyses, Pierre Janet, the pupil of the great Charcot, without pausing to mention those who with such brilliant success have followed similar lines. Janet's remarkable contributions marked the beginning of a new era of knowledge, and the data which they have furnished will be of enduring value. If they do not represent a movement capable of indefinite expansion it is because they have been of the nature of studies into this or that special problem of medical psychology rather than recognitions of typical facts lending themselves readily to great philosophic and sociological generalizations.

As examples of the *therapeutists*, the men of practical instincts, I need only mention Charcot, Weir Mitchell and his followers, and such men as Liébault, Bernheim, Van Eeden, Forel and Dubois. These names stand only for a few men out of hundreds and of course those who bore and bear them were not exclusively therapeutists.

Finally, we come to the third group of investigators, whom I have designated as *analysts, inductive reasoners and broad thinkers*. The foremost representative of this group,[2] at the present day, is unquestionably Sigmund Freud, a remarkable personage, whose observations and whose method [3] have opened for us avenues of inquiry into which men of the best minds are pressing forward in ever increasing number. No future student of human character and motives, whether these be called normal or morbid, will ever make studies deserving serious recognition without familiarizing himself with the researches of the school of thinkers and observers of which Freud was the leader and is still the central figure. Janet's work and that of men following similar lines (Morton Prince, Sidis, etc.) have made a revolution in the field of scientific psychology; Freud's work has extended this scientific revolution and has set on foot an equal revolution in character-study, educational psychology, race-psychology, child-study and folk-lore.

The Freud method (to which the name of " psycho-analytic " has been given) does not depend for its therapeutic success upon the ability of the physician to hypnotize his patient or of the patient to subject himself to the hypnotic influence. It is not an effort to spread the healing mantle of any " suggestive " influence over the painful details of the case. It is an attempt to enable the patient to penetrate with tireless zeal, increasing skill and fearless honesty, upon the details of his own emotions, life and thought, in the belief that nothing becomes less sacred or fails to become less painful, through being clearly seen. Such being its purpose it is hard to see why this method can justly challenge the hostility of any conscientious person, though easy to see why many physicians should shrink from the difficulties attending its successful application. "Suggestion," "isolation," improvement of the bodily nutrition, persuasion, explanation, all of which have their valued place, leave many of the great springs of emotion and of motive entirely untouched. They make no adequate effort to base themselves on any deep knowledge of human nature. Their influence, however important it may be, is bound to be limited in its scope.

The psycho-analytic method does not indeed necessarily give us all that we may need for spiritual progress, but it prepares the way and opens a long path. It does not exclude the other modes of treatment, but supplements some of them and often renders all of them unnecessary. If the slogan of the suggestive psychotherapeutics has been, " You can do better if you *try*," the distinctive slogan of this method is " You can do better when you *know*."

But when you know what? The answer has been already given, " When you know yourself." The symptoms of the psychoneuroses,—morbid fears, irresistible impulses to thoughts and acts, distressing doubts, nameless apprehensions,— and not these symptoms of illness alone, but also their congeners, selfishness, envy, suspicion, and temptations to cruelty and prejudice such as have filled the world with misery, have been largely the outcome of self-ignorance, in the sense that in this ignorance, the deeper sources of which have been, until now, imperfectly defined and largely unsuspected, lies the secret of the occurrence of these evils. It is the removal of this ignorance and the implantation of the desire as well as the ability to see things as they are that constitutes the best and only radical treatment.[4] This treatment, too, has its practical

[2] It will of course be understood that I am speaking of leaders in psychoneurology alone.

[3] Strictly speaking the originator of the psycho-analytic method was Joseph Breuer, Freud's older colleague and co-worker.

[4] Each person may be conceived of as representing the community in microcosm and the social sins of hatred, etc., represent conflicts between different aspects of our past and present selves.

limitations, but these are rather incidental to the difficulties of application of the method than inherent in its nature. It is a necessary condition for the therapeutic success of this method of radical re-education that the patients should be reasonably intelligent, not too old and inelastic, absolutely honest, absolutely unreserved in dealing with their physician, ready to join him in the inquiry, prepared to confide absolutely in his reliability and good faith. It is necessary, likewise, that the physician should be confident in his own motives and that he should have had a special training and special interest in this sort of psychological research. In other words, this kind of investigation, which seeks at once to discover the causes of the disorder and by that very fact to apply the remedy, implies a high degree of skill and training, or of natural aptitude. It is not, therefore, well adapted for the general practitioner or for the run of hospital patients, and no one should enter on such a course of treatment in any given case without being prepared to carry it to the end. If he does so he may find himself standing aghast at the task before him, as Faust stood before the Earth Spirit which his magic arts had summoned. But even though the general practitioner does not use this method, every physician should understand its scope and meaning, just as every physician should know the principles of many bacteriological procedures which he can never use.

It is important to note that the generalizations of which I shall now speak were worked out laboriously through the direct and prolonged questioning of many patients and the combined observations of many men, partly pupils and followers of Freud, partly independent workers in a much-neglected field. (Havelock Ellis, Krafft-Ebing, Moll, Fliess, etc.

I spoke a few moments ago of the "tumults of conflicting emotions" and also of "self-ignorance" as being the causes of the psychoneurotic symptoms. Both of these terms need amplification and explanation.

Before any one could be said to really know himself it would be necessary for him to know all the experiences, thoughts and emotions which he had had since birth. Of course this is impossible, but he might at least know them, or be able to summon them into the focus of his consciousness, by groups and samples, and every one would admit that a person did not know himself even tolerably well who had, either deliberately or in obedience to some blind impulse, selected certain groups of experiences, thoughts and emotions which he chose to take as standing for himself, and turned his eyes away from other groups, in spite of the fact that the rejected knowledge was of obvious importance. And yet this species of selection and rejection is continually going on with every one of us. It takes place also, and on a large scale, with communities and nations, and one of the chief functions of education and civilization is to obtain their rights for important groups of experiences, thoughts and emotions which had been repressed and rejected from the light of conscious knowledge.

We say we "cannot bear to think of"—and so strive not to think of—one or another matter, when in fact it is self-interest, or laziness, or blind obedience to an artificial code of social rules that really impels our choice.

Magna Charta, the abolition of slavery, the change of sentiment as to promiscuous almsgiving,—every true reform,—were all wrung from persons possessed of a certain power to maintain their views against the Cromwells and Washingtons and Wilberforces that rose up vigorously against them. The Cromwells are often narrow, too; they also are but partial knowers of themselves. But one great reason for their success is that they represent arguments the truth of which upholders of the established order already have divined but will not formulate to themselves or listen to when adduced by others.

And so it is with our own conscious attention in its dealing with rejected thoughts. We prefer to accept the established, traditional opinion rather than to investigate and think; we prefer, if need be, to show anger and bigotry rather than investigate and think; and yet we, too, divine the truth. For, be it clearly understood, the experiences, thoughts and emotions which we reject because they do not fit into the scheme of life which we select are not so far out of our minds as we suppose. We do not like to think of them, we do not dare perhaps to think of them, we say we do not think of them. But they are in our memories and in our minds, and they influence our acts; and it is the half-consciousness of their presence, and the fact that they represent deep instinctive cravings of our natures, in spite of our assumed hatred of them and our shrinking from them, that induce such emotions in us as anger and depression and envy and prejudice and jealousy and fear, and the impulse to adopt ceremonies and observances which are practically analogous to pagan ceremonies of propitiation and expiation. Indeed, the whole fabric of mythology is built on the projection outward of the sense of war and tumult and revolt and victory going on within ourselves between the thoughts and emotions which we clearly formulate and those which we only half or a quarter formulate and those which we do not formulate at all and affect not to know, yet which in reality influence our acts and thoughts.

Now, the leaders of the psycho-analytic movement have shown that these attempts to conceal ourselves from ourselves lead to mental conflicts and to illness and to false standards of civilization. They are insisting that those who wish not to be invalids shall not be encouraged to hedge themselves behind their lack of knowledge or their unwillingness to think or the divine right of some conventional code of morals, without its being made clear to them that these artificial rights are waging war within their minds with instincts older than morals and standing in no necessary antagonism to morals.

There is a sacredness in traditional customs,

the filtered wisdom of the ages, but there is also a sacred right to revolt against them and a sacred obligation in either case not to act or think without a reasonable knowledge of the facts. The typical signs and symptoms of nervous invalidism of the type that is now before us are really covers and substitutes instinctively adopted for the purpose of putting aside (concealing) thoughts, emotions, cravings and longings of forbidden sorts, or of sorts that it hurts one's sense of pride to face. They are all symbolisms, analogous to the symbolisms of dreams, and like them they point, for those who can read their hieroglyphic language, at the desires and repressions which are the real facts at stake. These thoughts and desires, half-formulated or unformulated, cause a sense of deep distress, for which the patient instinctively seeks reasons to account. Led by this instinct he adopts the figment of a fear of bridges or open windows or of railroad trains or of an impulsion to do injury to some one. In these symptoms, distressing though they are, the patient expresses in a rough fashion the cravings in which they had their birth; and for that reason he clings to his fears as to something which has the sacred fascination of a relic, though not realizing that he does so. If he would get well he must learn to see this, and for this purpose his *entire life*, and not merely the latest phase of it, must be made as transparent as glass, so that he may be able to see the whole of it at one glance. It will then appear that it is his own thoughts of which he is afraid and that his present fear has been preceded by other fears, the outcome of the same and other sets of mental conflicts, dating back, many of them, to days of childhood. To state the facts again in other words, his present fear represents a state of mental distress which arose as an expression of the fact that his thoughts or emotions relating to some important subject or subjects had become intolerable to him, and the open window, the bridge, the railroad train serve simply as so many molds into which the patient instinctively seeks to compress his vague and apparently causeless distress and so to explain it, even though erroneously, to himself. Every one recognizes that a bridge is a place from which people sometimes jump or fall, that a train journey is a common cause of accidents, that to be "shut in," whether actually or morally, has a certain element of the unpleasant. For reasons such as these, and perhaps many more, the situations indicated are really seized upon as excuses for the fears, simply because some excuse must be found. The patient, recognizing that he must find some way of accounting for his distress, instinctively grasps at causes which his neighbors would recognize as reasonable. This method of explaining the genesis of morbid fears is not a piece of *a priori* argument, but a mode of reasoning arrived at by questioning the patient's own experience and emotions. At first the patients do not see its logic, but gradually the truth enforces itself upon them and makes them able and willing to see themselves in a new light and to learn to substitute an intelligent scrutiny for an endless chain of morbid introspection. The physician who helps to make this scrutiny soon comes to realize that no symptom or trait of character can be adequately understood except on the basis of a relatively complete knowledge of the patient's whole environmental and emotional life since infancy. As this knowledge grows gradually wider and more accurate the element of time seems gradually to be eliminated from the history; infancy and age become approximated; the cause and the result are seen at one glance and as if coalescing; the present act, which one might have felt tempted to characterize roughly as selfish or cowardly or criminal, is seen as the logical expression of a repressed but natural instinct or of a misconception, formed in childhood but witnessed as if now living and active.

The immense significance of that rapid but hidden transition from babyhood with its animal instincts and emotions[5] to the later periods with their artificial morals and conventions is now for the first time clearly recognizable, through this process of rendering the whole life transparent, and its intensely dramatic features are susceptible of being clearly understood.

Then, as the research goes further, several other principles gradually get developed. The occasions on which these intolerable mental conflicts arose for which the fears were substituted are found to have been not one or two alone, but many and of various sorts. The recognition of this multiplicity of emotional traumata is an important supplement to the commonly accepted principle. A patient has a railroad accident, for example, or some severe emotional excitement, and these events (which in themselves involve considerable mental conflict) are considered as the sole and sufficient cause of the symptoms that result. But when his history is well analyzed many other events are found, different in appearance from the last, but psychologically of like import. "To fall," "to be overpowered," to "suffer loss," "to be in danger" are terms which apply to many emotional as well as physical situations of the most varied sorts, and such as every one has been exposed to not once alone, but many times, and the unconscious memories of these rush in, impelled by the force of mental association, to lend a new fulness of meaning to the railroad accident and to receive a new fulness of meaning for themselves from it.

But is there no difference in significance and standing between these various related and associated memories? Are there not some that have more power for harm as centers of emotional stress? The inevitable answer is (however gradually it may come to the surface in a given case) that those emotional conflicts have the greatest power to give a tone or color to the rest into which we originally put the deepest essence of ourselves, our strongest hopes, our most personal and secret and, therefore, most strongly repressed longings,

[5] This transition from the non-social period of infancy to the more and more social states of normal childhood and adult life, a transition in which the moral sense is first developed and when, therefore, an unfavorable judgment must be passed (of course unconsciously) on many antecedent acts and feelings, is of great importance for the whole theory of character formation and symptom-production. It hints, likewise, at a sort of biological basis for the doctrine of "original sin."

the feelings in which not only the prudent wishes of adult life, but the deep, uncensored cravings of infancy and youth could find expression. In other words, it is the emotions related to the great functions of reproduction, the sexual functions, that hold this position of prominence as giving color to the rest. It is in the conflicting tides of feelings of sexual origin, at which all romances, almost all imaginative and dramatic literature, love to hint, some prompting to intense expression, others to equally intense repression, all of which meet in fierce antagonism around the sexual instinct, that the real cause of nervous symptoms should be sought. But this should be understood with reference to the principle just stated, namely, that a vast number of emotions take their tone and value from the strongest or most fundamental one among them, just as a large school of artists may get its name from that of their greatest representative. It is only when this point is grasped that we can meet the objection of those who urge a host of other motives and emotions as of equal rank with those of sexual nature. So far as our conscious awareness is concerned, they may be of even higher rank. For the time when the sexual craving was so strong may have been in the forgotten period of infancy, and even then these cravings may not have been recognized as sexual at all. It may be only through our reasoning that their true nature is revealed. And yet they may have been intense enough to have founded the emotional traits of character which came, later, to be represented in the mental struggles from which, first the distress, later the specific fears and illnesses emerged.

It is not, then, necessary that every nervous invalid should accuse himself of having been "sexually inclined" in any objectionable sense, although it ought to be interjected here that the germs of the sexual perversions and inversions which when developed into an exaggerated form we characterize as criminal or morbid, are found in normal infancy and even in normal adult life. All these psychoneurotic illnesses, it cannot too often be repeated, are caricatures of normal tendencies. It is this which justifies the designation of them as "functional." This point is not brought forward as a mere bit of academic quibbling, but as a matter of the most practical importance. The infant is at first sexless, or, rather, both sexes are equally represented in his emotional life. It is often as natural to him to love *and love intensely* persons of his own sex as those of the opposite sex, his parents as those not standing in this relationship to him. Such intense love may reappear later in an exaggerated form and may lead to exaggerated expression of various morbid sorts. Children often exhibit a passion of objectionable intensity for teachers of their own sex, or for older children, and teachers for their pupils, and the exaggerated passion of children for parents may lead to relations of dependence, of instinctive imitation, of "identification," which dwarfs and limits their own development, or helps to foster the seeds of nervous invalidism in them, to a remarkable degree. It is interesting to recall, in this connection, that young children when passing through the period of transition from their "sexless" state to that of girlhood and boyhood, and, still more, when impelled by vague memory of that period, sometimes dream of themselves as of the opposite sex or as uncertain to which sex they now belong.

Two questions naturally present themselves to one who hears the merits of this psycho-analytic method described for the first time; first, Does not all this questioning about past matters lead to morbid introspection? then, supposing all these hidden facts have been obtained, What next? Where does the therapeutic influence come in?

To one who has become practically familiar with the working of this method these questions present no great difficulty. So far from morbid introspection being caused by this treatment it is prevented by it. Every patient is forced by the very terms of his illness to dwell upon his symptoms; he rolls them continually over in his mind like the tunes of a barrel-organ and without ever arriving at a satisfactory conclusion. The method of investigation which is here described substitutes an interested search, an intellectual inquiry, for this emotional treadmill of false reasoning.

As regards the therapeutic value of the method, much the same answer will suffice. The mental conflict to which I have referred, and which results in all the morbid symptoms, goes on without the patient's knowledge — although half-divined. The cure consists in bringing these unconscious processes to the light of reason. In their own nature they are imps of darkness and lose their power for harm when brought into the light. To be sure, it is not enough that this knowledge should be mere lip and ear information. Even this is something, but for the best result the knowledge of the truth should soak into the mind and express itself in the acts and become an integral portion of a new and reformed personality. In proportion as this is accomplished, the person in question approaches towards the desired knowledge of himself. He may still feel, and should still feel a craving for some further self-expression, a desire to take others, in increasing number, into the circle of his thoughts and interests and affections. But this craving will no longer tend so strongly to clothe itself in infantile, utterly personal and sensuous forms, which excite a feeling of mortification and the need of repression and suppression and expiation. The obsession of killing some person whom one really loves, of throwing oneself dramatically from an open window, are pretty certain to be recognized as ludicrously caricatured survivals from the days and phantasies of childhood; a railroad train takes its proper shape as a convenient means of locomotion.

It is, of course, clear, and clearer far to me than you, that this address is anything but complete. For one thing, I should have been glad to discuss further the important fact that much of the explanation for our mental conflicts, in which the symptoms of these maladies originate, takes place

wholly or partly within the bounds of that limbo which we call our unconscious mental life. Volumes might be written, also, with reference to the great struggle between instinct and social culture which, while it is responsible for civilization and progress, is responsible also for repression, bigotry, illness, misunderstanding and misjudgment of others and ourselves. Our cultural life with all its virtues is far narrower and more narrowing than most of us conceive. To broaden some of its tendencies should be our earnest effort, and to this great aim the art of psycho-analysis is partly consecrated. We should learn to deal less in moral judgments and more in knowledge. Moral judgments are, to be sure, needful for the rough exigencies of social life, as precursors of the jail and as affording protection against obvious practical evils. But for the scientific thinker they are out of place. The phrase "*tout comprendre est tout pardonner*" is not indeed applicable to the whole situation, especially in the case of the person mainly concerned. No one should wish to deny moral responsibility for his acts and thoughts. But it is nevertheless true that to "know all" is often justly to modify our judgment and our means of progress.

The familiar sins of "incontinence, violence and malice" which Dante punishes in his Inferno as attacks upon social stability and progress might justly be described in medical terms as equivalent to psychoneurotic symptoms; and in the sufferings and joys of those whom this great student of human nature sets toiling up the hill of Purgatory it is possible to read the symbolized history of that typical and desirable sort of convalescence from the miseries of nervous illness which leads not only to a better personal health, but to a wider sense of social opportunity and obligation. The community is the individual written large, and the so-called normal individual resembles the psychoneurotic invalid, but with the difference that he has learned, either instinctively or consciously, in infancy or in childhood or in later years, to establish a harmonious cooperation amongst the dominant tendencies of his mental life, or — what is the same thing transferred to another field of action — to adjust himself to some workable conception of community life. The invalid is he who is roughly studying this important lesson and within whose mind the struggle is still going on between native instincts, on the one side, and the forces arrayed to establish and maintain a series of moral and social standards imposed by the traditions of a conventional community, upon the other side.

If this thesis is correct, the physician's task broadens into that of reviewing these moral and social standards themselves and studying into the question of their justice, their desirability, their real origin. The sociological significance of the physician's task, as he studies nervous invalidism, is seen to take on a new importance in view of these considerations. The mischief which may be done by the ill-regulated emotions and prejudices of a "normal" person is always painful to contemplate. But there are many narrow and cruel social codes and customs, not only of the middle ages, but of the present day, which are of the same origin with these private prejudices, sins and symptoms. To labor against both sets of ills and for a better private and public status, is a worthy aim, and if the method of investigation here advocated can contribute towards this end it should be warmly welcomed and the labor which its application involves in any given case should be considered well-rewarded.

Furthermore, what applies to the neurologist applies almost equally to the patient. Nervous invalids should regard themselves not solely as persons in misfortune, but also as persons in position of opportunity and trust; they should feel themselves members of a band of investigators working in a great field, and as in a position to utilize their individual experiences, even though painful, as data towards the solution of a problem of universal interest.

A CONTRIBUTION TO THE ETIOLOGY OF ACTINOMYCOSIS. THE EXPERIMENTAL PRODUCTION OF ACTINOMYCOSIS IN GUINEA PIGS INOCULATED WITH THE CONTENTS OF CARIOUS TEETH.

BY FREDERICK T. LORD M.D., BOSTON, MASS.,

Instructor in Clinical Medicine, and Visiting Physician to the Clinic in the Harvard Medical School; Physician to Out-Patients, Massachusetts General Hospital.

1. SUGGESTIVE PREVIOUS WORK.

J. ISRAEL [1] noted the presence of carious teeth in three of five cases with actinomycosis. In one of the three he succeeded in demonstrating the parasite of the disease not only in the pus of a subperiosteal abscess of the lower jaw, but also in the root canal of an extracted, neighboring and carious molar tooth. He inferred that the parasite was harbored in carious teeth. No mention is made in his publication of the presence of the organism in the teeth of any of his other patients or in individuals without the lesions of actinomycosis.

The first extensive studies on the biology of the micro-organism of the disease were made by Bostroem [2] and by Wolff and Israel.[3] Their widely different views are responsible for much of the confusion which has since prevailed.

Bostroem's opinion that both man and animals are infected from sources without the body by the implantation within the tissues of grains, especially barley grains or their fragments, has received general acceptance. It is now known, however, through the masterly work of J. H. Wright [4] that Bostroem and many subsequent investigators, beginning their experiments with material containing true actinomyces, have in many instances cultivated therefrom a group of organisms properly classed among the Nocardia. Organisms of this group are widely distributed

* This investigation was undertaken under a grant from the Proctor Fund of the Harvard Medical School.

FIG. 4. "Clubs" with central filaments (x 1500).

in nature, being found not only as an occasional cause of suppurative lesions in man and cattle, but also on grains and grasses. They grow well on all culture media and in the incubator. They have never been shown to cause lesions like actinomycosis after experimental inoculation of animals.

Wright confirmed Wolff and Israel's findings and showed that one species of a branching filamentous organism could be constantly isolated from the lesions of the disease. This organism grows well only under anaërobic conditions and at body temperature. Characteristic colonies with peripheral "clubs" are produced by cultivation in such animal fluids as blood serum and serous pleuritic fluid (Wright). The intra-peritoneal inoculation of guinea pigs and rabbits gives rise to tumor growths having the histological appearance of actinomycotic tissue and containing typical club-bearing actinomyces granules. The organisms of the type described by Wolff and Israel and by Wright must therefore be accepted as the true cause of actinomycosis. Wright prophesied that actinomyces might be found as a normal inhabitant of the buccal cavity and the alimentary canal.

In 1904, while Wright was studying the biology of this organism and during my investigation of various bacterial infections of the respiratory tract, I noted the occasional presence in the sputum of organisms having the morphology and staining reaction of actinomyces. They appeared as isolated filaments or aggregations of filaments forming a small granule without "clubs" and much mixed with other bacteria. At that time I made unsuccessful attempts at isolation in pure culture. The subcutaneous inoculation of animals with the contaminated material grown in bouillon was also negative.

A recent review of the subject of actinomycosis again called my attentian to the uncertainty as to its method of origin. My previous finding of organisms resembling actinomyces in the sputum, the failure of true actinomyces to grow at other than body temperature and the lack of any convincing evidence that actinomycosis is a contagious disease suggested that infection arises from within the individual. The prevailing location of the disease about the jaw or neck naturally suggests the mouth as a source. As it happened, in two cases with actinomycosis recently seen in consultation and in one patient seen at my office, I obtained a history of much trouble with the teeth preceding the onset of the affection. My attention was thus turned to the teeth as a cause.

2. INVESTIGATION OF THE CONTENTS OF CARIOUS TEETH.

(a) *Method.* No patients with the lesions of actinomycosis were selected for study. From about three hundred patients recently examined, the contents of carious teeth were removed in 16. The material was lifted or scraped from the tooth cavities by means of a spatula and placed in sterile glass tubes. It was carried at once or within a few hours to the laboratory. Cover glass preparations were made from a part of the material in 11 cases. Cultures were prepared in most of the cases both in bouillon and in sugar agar suspension tubes. Pure cultures have not as yet been obtained. The culture experiments are not completed and will not be described at this time. A third portion in 5 cases was hardened and cut in serial sections. In 9 cases a portion of the material was placed in a glass dish containing a small amount of bouillon, divided into particles small enough to pass through a rather large bored needle of the injecting syringe and inoculated intraperitoneally into guinea pigs. All instruments used in the experiments were sterilized immediately before they were used. The inoculated animals were kept in separate cages.

That part of the contents of the cavities set aside for sections and the tissue obtained from the inoculated animals were hardened in alcohol, imbedded in paraffin and cut in serial sections. Great difficulty was at times experienced in obtaining a complete series because of the presence of numerous small, hard, foreign bodies. These indented the knife and tore the sections. The sections were stained with a weak solution of eosin, followed by Gram's stain, decolorized with equal parts of xylol and aniline oil, cleared with xylol and mounted in balsam.[5]

(b) *Cover glass preparations of the contents of cavities.* In smear preparations from cavities in all of 11 cases, Gram staining filaments mixed with other bacteria were found. The filaments stain deeply and evenly or present deeply stained points at intervals, giving them a beaded appearance. In places, small dense aggregates of filaments are seen. The filaments are for the most part slender and wavy. Both long and short forms are observed. Short, bent, bacillus-like organisms are not infrequently seen. The identity of these filaments with actinomyces is suggested by their similarity in appearance with the forms of that organism found in smear preparations from pure bouillon cultures. Branching is in rare instances seen in the isolated and clustered organisms. In the manipulation necessary for the preparation of smears from pure cultures of actinomyces grown in bouillon, the branches of the filaments are usually detached from the parent stem and appear as unbranched long or short filaments. The infrequency of branching forms in the cover glass preparations from the contents of carious teeth is probably due to the manipulation of the specimens. Neither in the fresh material crushed between cover glass and slide nor in the stained preparations have true "clubs" been found. At times an increase of the filaments toward one end is seen.

(c) *Serial sections of hardened masses of the material.* Serial sections were studied in 5 cases. By this method, the morphology of the organisms and their relation to the material in the cavities can be more satisfactorily determined. Branching organisms having the morphology and staining reaction of actinomyces were constantly found.

[5] This is practically the same as Mallory's Method No. 1. Mallory and Wright's Pathological Technic, second edition, 1901, p. 365.

The filaments are isolated or form small or large colonies resembling the colonies of actinomyces grown in bouillon or sugar agar suspension tubes. In some instances, they are found in great numbers within what appears to be a degenerated mass of organic material, at the margin of which is a dense network of more deeply staining organisms. From the marginal zone, radially disposed and at times swollen filaments project into the neighboring detritus. Such an appearance closely resembles the colonies of actinomyces in actinomycotic tissue. No "clubs" have been found about these colonies.

The number of organisms having the morphology and staining reaction of actinomyces both in the smear preparations and in the sections is variable. In some preparations they are present in great numbers and far outnumber other bacteria. Such an appearance suggests that actinomyces plays a fundamental part in dental caries.

Actinomyces grows best in artificial media under anaërobic conditions. The organism is not, however, an obligate anaërobe and multiplication in carious teeth is doubtless favored by growth in symbiosis with other bacteria and the reducing action of organic matter.

(d) *Animal inoculation.* Only five of the nine animal experiments are completed. A positive result in three of the five, however, justifies a preliminary report at this time.

The animal inoculated with material from Case I died at the end of six days.[6] The remaining animals were killed at intervals of twelve, twelve, seventeen and nineteen days respectively. All showed thickening of the omentum with the formation of tumors. From two to eleven hard tumors varying in size from about that of a pin's head to a lesion 12 by 5 mm. and of an oval, spherical or irregular contour were found in each of the five animals in the series. The tumors were slightly reddish in color. They were resistant on section and the cut surface was reddish, grayish or white. In all cases, the lesions were connected with the great omentum and for the most part were adherent to the stomach. Tumors were also found adherent to the root of the mesentery, the abdominal wall and the intestine. The formation of free pus in the nodules has not thus far been observed. No invasion of the glands by branching filamentous organisms was noted.

In the animals inoculated with material from two of the cases (Cases III and V) there was only slight thickening of the omentum and a few nodules not exceeding a pin's head in size. In the thickened omentum and the small nodules, numerous bacteria and foreign bodies invested by connective tissue were found, but no colonies of branching filamentous organisms.

In the animals inoculated with material from the three remaining cases (Cases I, II and IV) there was greater thickening of the omentum and more numerous and larger tumors. Colonies of branching filamentous organisms were found in these lesions. The colonies were surrounded by a zone of pus cells of variable width, beyond which there was round-celled infiltration or well-developed connective tissue. The extent of the inflammatory reaction about the colonies was large compared with the width of the colonies. The number of colonies in each tumor varied from one to five or six. The size of the tumor appeared to vary with the size or number of the colonies, being larger in the presence of single large or several small colonies. The colonies themselves varied in size from those discovered only after careful search with the oil immersion lens to a granule several times the diameter of the colony shown in the photograph. (Fig. 1.) They were composed of a network of slender, branching, Gram-staining filaments. The larger colonies showed a dense mass of faintly staining beaded filaments surrounded by a narrow margin of more deeply and evenly staining organisms. At the periphery of the colony isolated, radially disposed, swollen filaments projected in some instances to a considerable distance into the neighboring tissue. The peripheral filaments were often invested with a club-shaped eosin-staining mass. These "clubs" some of which show a central filament may be seen in the photographs. (Figs. 2, 3 and 4.) "Clubs" were demonstrated about some of the colonies in all the three positive cases. In the first two cases (Cases I and II) the clubs were small in size and number. In the third positive case (Case IV) they were numerous and of large size.

Bacteria and foreign bodies were also found in the lesions. In one instance (Case IV), a dense network of filaments with peripheral "clubs" was seen to have developed about a foreign body.

In their histological appearance, the lesions are identical with actinomycotic tissue. The colonies of branching filamentous organisms are typical actinomyces granules.

A brief account of the inoculation experiments in the five cases is as follows:

CASE I. *Positive.* M. L., female, age twenty-nine. Hospital No. (O. P. D.) 150775. Clinical diagnosis: Salpingitis. Material obtained from a carious first molar in right upper jaw. Guinea pig inoculated June 3, 1910. Died. Interval six days. Autopsy June 11. Great omentum much thickened and injected and contains two hard nodules about 4 mm. in greatest diameter. A third nodule 2 to 3 mm. in diameter firmly adherent to the root of the mesentery and connected with the great omentum by a narrow band of connective tissue. Serial sections of the three nodules show in one, two colonies without clubs. In a second nodule a large colony with clubs. The third nodule is composed of inflammatory tissue and is without colonies of actinomyces.

CASE II. *Positive.* H. T. G., male, age fifty-nine. West Medical Service. Hospital No. 170194. Clinical diagnosis: Pyonephrosis. Gastric irritation. Material obtained from between lower middle incisors which are carious and neglected. Guinea pig inoculated June 3, 1910. Killed June 15. Interval twelve days. Autopsy showed thickening and injection of the omentum which contained two nodules about 2 mm. in greatest diameter and several smaller nodules. In this case, the entire omentum was folded together and cut in serial sections,

[6] Aside from the specific lesions to be later described this animal showed a diffuse peritonitis.

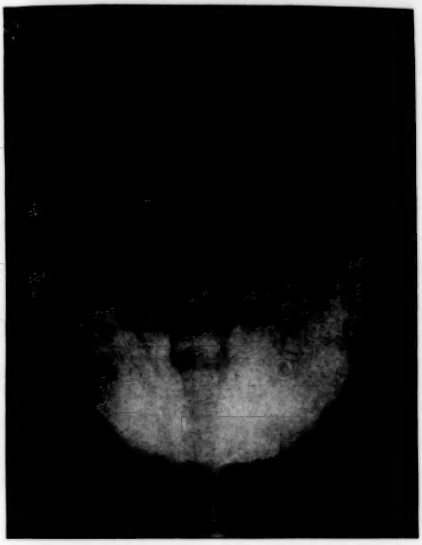

FIG. 1. X-ray of Case I. Tube in common position for stone in the lower portion of the ureter. A fair plate totally negative.

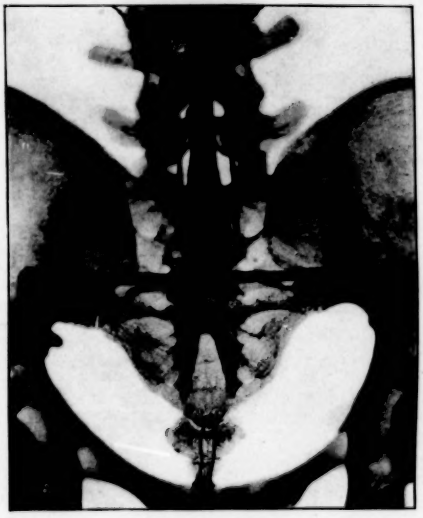

FIG. 3. X-ray of skeleton with calculus removed from Case I placed on the bone in the line of the ureter.
Note that calculus is practically invisible under extremely favorable conditions.

FIG. 2. X-ray of calculi removed from Case I and Case II.

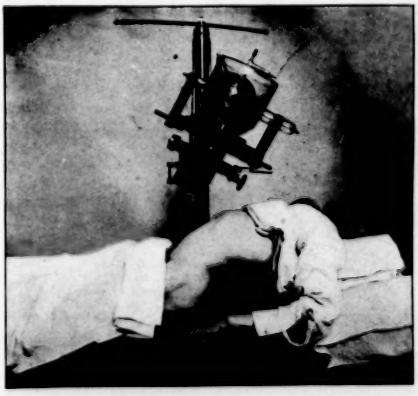

FIG. 4. Showing relative positions of patient and tube used in taking Figs. 5 and 8. The Edebohl's bag is placed under the lumbar vertebræ to give obliquity to the lumbar spine while removing the patient's face from the neighborhood of the tube. Distance from anode to plate, 30 in.

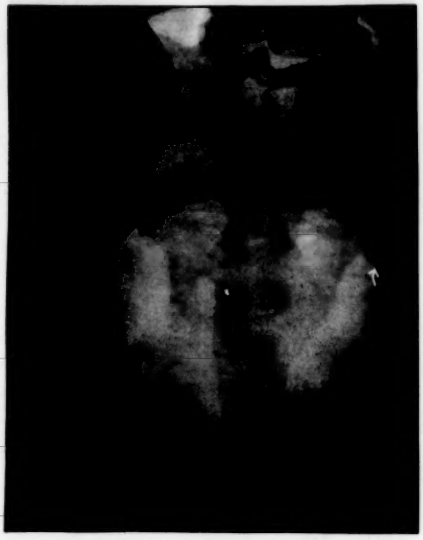

FIG. 5. Plate of Case II, taken in position shown in Fig. 4. Position of stone indicated by arrow.

FIG. 7. Plate of the same specimen as Fig. 6. Tube placed in oblique position and skeleton moderately inclined. Note that two shot have been displaced into the pelvis; also the foreshortening of the sacrum and the changed relation between the transverse process of the fifth lumbar vertebra and the top of the sacrum.

FIG. 6. Plate showing skeleton with artificial iliopsoas muscle built up, on which were placed six lead shot just outside the normal position of the ureter. Tube focused exactly over shot. Note that the whole sacrum shows, and that the relation between the transverse process of the fifth lumbar vertebra and the top of the sacrum is on this side normal.

FIG. 8. Plate of the same specimen as Fig. 6. Tube and skeleton in relative positions shown in Fig. 4. Note displacement of all the shot into the pelvis and that the space between the shot is much diminished. The lower segments of the sacrum cannot be seen and the transverse process of the fourth lumbar vertebra now occupies the position held by the fifth process in Fig. 6.

Many small colonies without clubs are found in the sections. Two fairly large colonies with clubs are found in the larger nodules.

CASE III. *Negative.* D. R., male, age forty-six. West Medical Service. Hospital No. 170106. Clinical diagnosis: Myocardial insufficiency. Arteriosclerosis. Material obtained from many carious stumps in upper and lower jaw. Guinea pig inoculated June 3, 1910. Killed June 15. Interval twelve days. Autopsy showed only very slight thickening and no injection of the omentum. Two nodules smaller than a pin's head were found. Examination of the remainder of the omentum pressed between two glass slides shows under the low power of the microscope numerous small cellular areas. Serial sections of the entire omentum and the two nodules show inflammatory tissue, but no colonies of actinomyces.

CASE IV. *Positive.* T. W. J., male, age twenty-eight. East Medical Service. Hospital No. 170123. Clinical diagnosis: Acute articular rheumatism. Mitral regurgitation. Material obtained from a carious molar in left lower jaw. Guinea pig inoculated June 14. Killed July 1. Interval seventeen days. Autopsy showed intestine and great omentum adherent to the site of the inoculation in the abdominal wall. The omentum is much thickened and contracted and contains near the point of the inoculation an ovoid mass about 12 mm. long and 5 mm. wide. The mass is made up of two fused nodules of about equal size and is somewhat constricted in the middle. The omentum is elsewhere adherent to the intestine in various places. It contains about ten other nodules varying in size from that of a pin's head to 3 to 4 mm. in diameter. The lesions are more numerous and larger than in the previous cases. Sections of the largest mass show two large and several small colonies. Club formation is well marked, as shown in the photographs.

CASE V. *Negative.* C. W., female, age forty-four. East Medical Service. Hospital No. 169939. Clinical diagnosis: Gastroptosis. Gastric dilatation. Material obtained from many carious teeth. Guinea pig inoculated June 14. Killed July 3. Interval nineteen days. Omentum very slightly thickened and adherent to the site of the inoculation. Contains one nodule smaller than a pin's head. Serial sections of the omentum and the nodule show inflammatory tissue, but no colonies.

3. SUMMARY.

Organisms having the morphology and staining reaction of actinomyces have been constantly found in smear preparations (11 cases) and in serial sections (5 cases) of the contents of carious teeth from individuals without actinomycosis. They are present in such numbers as to suggest that they play a fundamental part in dental caries.

Following the intra-peritoneal inoculation of guinea pigs with the contents of carious teeth, omental tumors histologically identical with actinomycotic tissue and containing typical club-bearing actinomyces granules have been produced in 3 (60%) of 5 animals.

4. BEARING OF THE FINDINGS ON THE ETIOLOGY OF ACTINOMYCOSIS.

The constancy with which organisms having the morphology and staining reaction of actinomyces are present in carious teeth suggests that under certain conditions persons with carious teeth are liable to develop actinomycosis. Lack of free drainage of a tooth cavity whether arising spontaneously or as the result of filling an imcompletely sterilized tooth may be regarded as favorable to the production of the disease about the jaws or neck. In such cases the root canal of the tooth is the channel of infection. Organisms derived from the teeth may also be implanted in neighboring tissues or find lodgment in more remote parts of the body by way of the respiratory tract or the alimentary canal. Local injury of the tissue may be regarded as an important predisposing factor.

Although actinomycosis is doubtless more common than is generally believed, it cannot be regarded as of frequent occurrence. In explanation of its infrequency compared with the numberless chances for infection it may be suggested that invasion of the tissues by actinomyces and associated bacteria does not always give rise to actinomycosis. In the two negative inoculation experiments with the contents of carious teeth in the present series (Cases III and V) organisms resembling actinomyces were present in smears from the extracted contents and it may be assumed that actinomyces was also present in the injected material but failed to multiply in the body of the animal. Here, as in other infections, the varying numbers and vitality of the seed and fertility of the soil are of importance. It is probable that only in a small proportion of cases in which implantation of the organism occurs does it actually take root in the tissue and lead to progressive lesions, with club-bearing actinomyces granules.

The investigation was carried out in the Clinico-Pathological Laboratory of the Massachusetts General Hospital. I am indebted to J. H. Wright for helpful suggestions regarding technic and to the staff of the hospital for permission to investigate their cases. The photographs were made by Mr. L. S. Brown.

THE DIAGNOSIS OF STONE IN THE PELVIC PORTION OF THE URETER.*

A PRELIMINARY REPORT ON CERTAIN LIMITATIONS OF RADIOGRAPHIC DIAGNOSIS AND A SUGGESTED REMEDY.[1]

BY HUGH CABOT, M.D., AND W. J. DODD, M.D., BOSTON.

IN a recent scholarly monograph by Jeanbrau the following causes of non-visibility of calculus in the ureter by means of the x-ray are laid down.

(1) Faulty technic. (Absence of compression, tube of too high penetration, etc.)

(2) Chemical composition of the stone.

(3) Its small size.

To this must be added a fourth:

The position of the stone.

* Read at meeting of the American Association of Genito-Urinary Surgeons at Washington, D. C., May 3, 4 and 5, 1910.

[1] Report presented at the XIII Sessions de l'Association Francaise d'Urologie.

This fact was brought forcibly to our attention a few months ago by the two following observations which, coming close together, served to make the findings impressive.

These patients were seen at the Massachusetts General Hospital, and it is through the courtesy of Dr. S. J. Mixter and Dr. J. G. Mumford that we were enabled to look after them.

Case I. M. M. D., male, age twenty-four. Entered the hospital Feb. 16, 1910. Six years ago had an attack of painless hematuria, lasting two days. Two years ago another attack of hematuria also painless but followed by the passage of three small calculi. Two months ago colicky pain in the right lower quadrant of the abdomen. Pain shooting to the right testis and penis. Since that time has had several such attacks but no marked hematuria, though the urine has been smoky. Two weeks ago was laid up in bed for several days with a dull pain in the region of the cecum and was thought to have appendicitis.

Examination showed tenderness with some muscular spasm in the right lower quadrant of the abdomen, but was otherwise negative.

Cystoscopy showed a normal bladder with the orifice of the right ureter slightly larger than the left, but not otherwise abnormal. Normal urine from the left side, none from the right. Ureter catheter entered right ureter for nine and a half cm. and could be passed no further. Several x-ray plates were negative. (Fig. 1.) At operation a fair-sized calcic oxalate stone was removed from the ureter at the point where it crosses the iliac vessels. (See Fig. 2, Case I.)

The stone was then placed upon a skeleton pelvis as nearly as possible in the proper position and an x-ray plate taken, which again failed to show the stone. (Fig. 3.)

Thus we have a calculus of fair size, of high density, studied with good technic by an expert and yet totally invisible.

On Feb. 25, 1910, C. C. B., male, age forty-two, entered the hospital with the following history: Seven years ago pain in the right loin and side. Hematuria for several days, followed by the passage of several stones. Well until ten days ago when he began to have pain in the right side similar to but not so severe as the previous attack. This was accompanied by moderate frequency of micturition, amounting to three to five times at night. No blood. Pain lasted two days and then disappeared, but the frequency of urination continued and the urine contained pus. It was for this that he applied for treatment.

General physical examination negative. Series of good x-ray pictures was negative. The urine was pale, cloudy, alkaline, 1013, albumen slightest possible trace, sediment, mostly pus with rare red blood corpuscle.

Cystoscopy showed bladder generally normal. Right ureteral orifice slightly thickened and slightly ulcerated. Ureter catheter enters the right ureter for 7 cm. A smaller catheter was then tried and passed 10 cm., but would go no further. Catheter passes the left ureter freely and draws normal urine. Indigo carmine excreted in nine minutes by left kidney, not at all by the right in an hour. Here again the diagnosis of stone seemed probable, and yet x-ray was totally negative. Believing that the stone occupied a position quite similar to that in the first case, and that if advantage were taken of the fact that at this point the ureter lies some distance from the bone on account of the thickness of the iliopsoas muscle, the shadow ought, so to speak, be thrown into the pelvis by taking the plate with the tube placed over the region of the umbilicus and focused obliquely downward into the pelvis. The relative positions of the patient and tube are shown in Fig. 4. Plates taken in this way showed stone (see Fig. 5).

At operation the stone was found lying over the iliac vessels in a position nearly similar to that of Case I, and proved again to be an oxalate calculus of rather large size and high density. (Fig. 2, Case II.)

These two observations led us to the following conclusions:

(1) That, even with good technic, stones of moderate size and high density may fail to show when they lie in the portion of the ureter lying in front of the sacro-iliac joint, if the tube be placed in the ordinary position.

(2) That some, at least, of the calculi lodged in this position can be detected by x-ray if the tube be placed in the position above described.

Since these observations the time at our disposal has been too short to thoroughly investigate the problems thus raised, but we have made certain investigations which seem to us at least suggestive, and we desire to submit them as confirmatory evidence.

We took a skeleton, built up an artificial psoas muscle and placed upon it a rubber tube containing six lead shot, in a position intended to correspond to that of the ureter, though as will be seen the position was not strictly accurate, but does not, we think, at all vitiate the results. The skeleton was then placed in the ordinary position and a plate taken with the tube focused over the shot. The result is shown in Fig. 6. With the position of the shot and the skeleton unchanged, the tube was then moved upward and focused obliquely into the pelvis, giving the position of the shot shown in Fig. 7. The tube and skeleton were then placed in the position shown in Fig. 4, but the tube was focused over the shot. (Fig. 8.) It will be observed that the shot are now clear from the bone, that their relative position is very much foreshortened, but that all of the shot show. This seems to prove that displacement of the shadow by this technic is possible, and that the displacement is sufficiently great to throw a shadow away from the bone and therefore render calculi of reasonable density visible.

The application of these observations to actual conditions depends chiefly upon the thickness of the iliopsoas muscle. A large muscle will make detection of calculi by this method relatively easy, while a thin muscle will make it difficult.

PREGNANCY, NURSING AND THE CARE OF YOUNG BABIES. AN EXPERIMENT IN PREVENTIVE MEDICINE.

BY MRS. WILLIAM LOWELL PUTNAM,
Chairman Committee on Infant Social Service of the Women's Municipal League.

THE object of the Committe on Infant Social Service of the Women's Municipal League of Boston has been to improve the efficiency of the future citizens by beginning with the health of the babies. A person without health may be a worthy object of admiration, but he is not so likely to add to the wealth or efficiency of the community as a healthy one, nor indeed is he likely to be as sane or as estimable a citizen; the ranks of the degenerates are mostly recruited from the physically unfit. It is universally accepted now that the illness of young children is one of the predisposing causes of lifelong debility. Von Behring says that in Germany only one sixth of the males born grow up fit for military service, or physically perfect, and this he attributes to infection derived in infancy from milk. With all due allowance for the exaggeration of a possibly one-sided point of view, this statement is very impressive. Believing that prenatal influences must be still more potent for good or ill over the child's whole future than even those of early childhood, the Committee have begun their work with pregnant women as early as they could be reached, and continued it throughout the first year of the child's life.

The work was undertaken for a year as an experiment with the hope that if it justified itself it would be taken over by other agencies. It began in April, 1909, with two nurses. The time of one nurse has been given almost entirely to the prenatal work, and the other wholly to babies under a year of age. The principal desire of the Committee has been of an educational not a philanthropic nature. It has been most anxious that the women helped should pay whatever they could toward the expense of the work and has tried to make them feel that in so doing they are making it possible to help more women as they themselves are being helped.

At the time of beginning in both of its lines of work, the Committee was practically a pioneer in Boston, and in the care of pregnant women but little has even yet been attempted anywhere else, which makes this branch of peculiar interest. This part of the work has been carried on with the help and encouragement of the Boston Lying-In Hospital. The names of those patients who are registering to become House-patients, and who are, by the way, of rather a better class than the Out-patients, are given to us daily, and immediately visited by the nurse in their homes. The first visit is necessarily one of making acquaintance and requires much tact, but the nurse is wonderfully gladly received, only one or two having refused her advice during the whole year, and to our great satisfaction the patients bring their friends to her for care, ten of our cases have directly come to us in this way, and possibly more. Some of those brought to us by their friends were to be Out-patients of the Lying-In Hospital and came to us in the early part of their pregnancy before they were allowed to register at the hospital. Out-patients, owing to lack of facilities, are not at present permitted to register till the seventh month. When they have reached their seventh month we have given them up to the Instructive District Nursing Association which cares for all out-patients during their confinement and afterwards, and also visits them beforehand when the funds of the Association permit. We have given them up to the Association, therefore, that there might be no duplication of work.

We never take cases coming to us for the first time within one month of confinement as we do not think we can help them materially when pregnancy is so far advanced; and we greatly prefer to have the women come under our care as early as possible. One case was brought by a friend in the second month of pregnancy and several were referred to us by the hospital in the third month, but on an average we have had the women under our care for only three months, which is perhaps all that can be expected in beginning such a work; we hope in time we shall get our cases earlier.

There have been no deaths during pregnancy, and no very serious illness. This we believe has been owing to the constant supervision of the health and the circumstances of the women. Three among them had such threatening symptoms of eclampsia that they were sent to the hospital, from which, after treatment for a few days, they were discharged well. Thirty-seven others who, though threatened with the same disease, were not ill enough to send to the hospital, were given advice at home. Nine cases yielded immediately to the treatment and the twenty-eight others after prolonged care were also cured. Beside these cases of threatened serious illness, about two hundred other patients were found to need the nurse's help in one way or another, for less grave troubles, and all whose whole term is yet completed passed through their pregnancy successfully. In the year there have been two miscarriages only among about four hundred patients.

The Committee want very much to make the work self supporting, and hope that in time this can be accomplished. They believe first that the work in this way could become capable of indefinite development; second, that every one appreciates much more what they pay for, and third, that there is a very valuable class of people, the most deserving of help in the community, who, although too poor to pay for the best professional advice, will nevertheless, not accept it as a charity, and who could in this way be reached without the loss of their self-respect. The payment for each case will have to be between $2.50 and $3.00. This does not seem a great deal to pay for months of care and would probably allow for some patients who were too poor to pay anything and yet enable the work to be self supporting.

The nurse has visited each patient at least as often as once in ten days whether she needed help or not, and if there was anything wrong she has been to see her as much oftener as necessary. One gratifying thing is that a woman who was our patient during her first pregnancy has come to us again even before registering at the hospital,[1] and many of the mothers at our healthy baby clinic have told me that were they to have another baby, they would be willing to pay for the care of the pregnancy nurse. Before giving up this work to be carried on by others we trust it will have become the custom for the women to pay what they can afford even if the whole sum is too large for their means.

Beside the pregnant women cared for, the nurse has also visited and greatly helped four other women whom she had cared for during their pregnancy. The babies of three of these poor women died before leaving the hospital, so that they never came under our other nurse's care, yet they were themselves not in a good state of health and needed advice, so that it seemed best to have them watched by the nurse, which has been most successfully done. It is satisfactory to be able to report that, incidentally to her other work, the nurse has been able to persuade five mothers to keep their babies with them, where before her visits they had intended to give them up.

The total number of women referred to the Committee by the Lying-In Hospital has been 477, of whom 40 could not be found at the address left at the hospital, and about 25 moved away later without leaving their address. These 65, although they were not helped, nevertheless took the nurse's time. Ten more have moved away during their pregnancy to places too distant to be visited, and in the cases where some further care was called for they have been referred to a suitable agency in the place to which they have moved. Twenty have been cases which have not been suitable for our care and have therefore been referred to other agencies here. We have never, in so far as we know, given up any case once sent to us without seeing that it was receiving the care it needed.

The largest number on our list at any one time has been 74, and the total number of visits paid to patients during the year, 2,518.

In connection with the work, we desire to call attention to the desirability and importance for our future citizens of the prevention of the employment of pregnant women in any hard work either shortly before or after childbirth. There are regulations in England already looking to this object.

Another matter to which the Committee want to call attention most urgently is the importance of licensing and properly inspecting midwives, for they believe that not only is there much unnecessary blindness and many other very serious complications, owing to lack of proper care at birth, but that if midwives were properly educated themselves and taught their duties in the way of educating the mothers, the work which this Committee has been trying to initiate would be enormously advanced.

The other branch of the work which has been carried on by the Committee was, as already stated, with mothers and babies, and for this purpose the Committee employed another nurse. As so much of this work was done with the help of the Infants' Hospital, the Committee accepted Dr. T. M. Rotch's choice of a nurse. Her duties were, as has been seen, primarily with healthy babies, but in return for the help given us by the hospital, the nurse visited, during the year, 89 of the sick babies discharged from the Infants' Hospital or from the Out-patient Department.

The work with well babies, which was by far the greater share, was carried on by means of visits to the babies in their homes, made, like the pregnancy nurse's, at least once in ten days and oftener if necessary, and added to these visits were fortnightly clinics held at the Infants' Hospital through the courtesy of Dr. Rotch and the kindness of Dr. Henry I. Bowditch. Dr. Bowditch was always there himself, which made the work much more valuable, as in this way the babies were followed more carefully than could have been done had there been a variety of doctors. Between 80 and 100 babies were carried through the summer without one case of diarrhea or indigestion. These visits and clinics began on April 1, 1909, and at that time there was no institution, so far as we know, doing exactly this sort of work in Boston. The Committee on Milk and Baby Hygiene began their work of instruction on June 24 of the same year, but the work of the two committees has always been somewhat dissimilar.

The babies cared for by the committee of the Women's Municipal League have been mostly infants referred to it by the Lying-In Hospital as soon as they left that institution (many of the mothers had been already cared for by the pregnancy nurse), or, in the case of out-patients, as soon as the doctors and district nurses gave up visiting them. Thus they were taken care of before anything had had time to go wrong, as our nurse immediately visited them, made friends, gave advice where needed and invited them to "The Healthy Baby Clinic," at which the attendance has been very fair considering how far away most of our mothers and babies lived. Even on the stormiest days we have never been without a patient, for one of our Italian mothers from the North End never failed to bring her baby, rain or shine, and the baby showed the result; he was, therefore, allowed the honor of being the first and the last at our demonstrations held at the 1915 Exhibit. Before beginning the clinics we thought it might be well to offer a prize to the baby who showed the best care, but we found prizes absolutely unnecessary. All the mothers took the greatest interest, not only in their own babies, but in one another's,

[1] Since writing this report, another of our earlier pregnancy cases who was most grateful for the help given her has sent to ask the nurse to visit her again for the same purpose. This case will be the first to be under our care for the full possible time, eight months, and having come back to us because of help received, the case is especially satisfactory.

and were so kind to each other and so sympathetic if something was wrong that anything that could cause rivalry would only have hurt the spirit which pervaded the meetings.

The babies who have been cared for, although not living in quite so wide a radius as our pregnancy cases, have come from the North, South and West ends, South Boston, East Boston, Roxbury and Dorchester, Charlestown and the nearer parts of Cambridge. These are considerable distances to carry a young baby, but one of our mothers did better still, for her husband's work took them for a time to Wakefield, yet she, feeling the benefit of our clinics, even brought the baby in from there. The average attendance was 9 and the greatest number on any one day was 17. The 14 who came to the last clinic before this work was handed over to the Infants' Hospital, at the end of our year of experiment, begged that the hospital might keep it up, saying that they would gladly pay all they could afford, some of them even offering to pay twenty-five cents at each clinic. This sum if contributed by all every fortnight would practically pay all the expenses of the nurse, and although this is too much to expect for a long time to come, yet it is an object greatly to be sought.

The total number of healthy babies referred to us by the Lying-In Hospital was 199, and 6 more were brought in by their friends. As in the case of the pregnant women, several gave wrong addresses at the hospital, others moved away and an occasional one did not want the nurse's visits; all of these cases together amounted to 50, reducing the number actually cared for to 155. One hundred and twenty-nine of these babies were breast fed, and to our great satisfaction in 10 cases where the mother's milk had apparently gone, it was brought completely back again simply by advice as to diet, etc. Thus only 26 babies had to be brought up by hand.

One interesting possible development of the work has been the probability of being able to provide good young mothers as wet nurses for delicate babies. One or two instances have occurred where the mothers had a superabundance of milk and were willing to do this, not so much with a view to the money that could be earned, as from a desire to help another baby to grow strong like their own. With care this might grow into a most useful institution.

The experiment seems to the committee to have proved itself of value. It is too early yet to see how great the permanent good will prove to be, but it seems as if it could not fail to have far reaching results.

The Bureau of Insular Affairs reports that the death-rate among the more than eight thousand government employees in the Philippine Islands for the quarter ended March 31 was 6.9 per 1,000 per year. Of these employees, some 3,700 are Americans, including the officials and employees of the insular, provincial and municipal governments, and the police and fire departments of Manila. — *Med. Record.*

LESIONS OF THE MAJOR TRUNK VISCERA IN EPILEPTICS.

BY A. E. TAFT, M.D.,

Research Officer, Monson State Hospital.

The prevalent idea that epilepsy has its origin, in man at least, in the higher nerve centers has had the effect of withdrawing attention from the remainder of the body. There is, moreover, in the nature of things, little hope that specific and peculiar epileptic changes will be found in such tissues as those of the major viscera of the trunk.

It may well be, however, that characteristic (if not specific) alterations can be discovered in the trunk organs. Such alterations if found would perhaps be effects rather than causes of epilepsy. It will be almost as difficult to prove, in any individual case, that such changes are epileptic effects as to prove that they are the causes of epilepsy.

It is, therefore, not the object of this paper to assert a correlation between the changes found in the trunk viscera and the epilepsy exhibited by the subjects examined. The object is rather to learn what material exists for possible correlations.

The protocols and tissues examined were derived from fifty epileptic subjects autopsied from the Monson State Hospital; the Danvers Insane Hospital, pathological service of Drs. Barrett and Southard; the Worcester Insane Hospital, Drs. T. A. Hoch and F. J. Tower, pathologists; Westboro Insane Hospital, Dr. S. W. Fuller, pathologist, and Taunton Insane Hospital, Dr. H. M. Miller, pathologist.

The statistics are chiefly based on the findings in the heart, lungs, spleen, liver and kidneys, although other organs were frequently available. The technic employed for routine histological examination was, virtually in all cases, fixation in Zenker's fluid and staining of paraffin sections by the eosin and methylene blue method (Mallory and Wright's Pathological Technic). Special methods were employed in particular cases.

Before proceeding to an analysis of the findings, the data from the individual cases will be presented in condensed form:

Case I. No. 893. Male. Admitted June 4, 1904. Birthplace, Ireland. Onset of epilepsy at sixty-two. Assigned cause, alcohol. No heredity. Grand and petit mal attacks. Duration, thirteen years. Has had ordinary diseases of childhood. Physical examination negative except demented appearance, poor teeth and loss of knee jerks. Nov. 20, patient complained of stomach trouble and appeared cachetic. Examination showed enlarged liver. Died Nov. 23, 1905. Age, seventy-five years. Cause of death, cancer of liver.

Microscopical. — Heart: Slight fibrous myocarditis and arteriosclerosis. Spleen: Marked congestion. Thickened arterial walls contain hyaline. Liver: Papillary adenocarcinoma. Kidney: Chronic interstitial nephritis with arteriosclerosis.

Case II. No. 1376. Male. Admitted Oct. 1, 1907.

Birthplace, Massachusetts. Onset at three years. Cause unknown. No known heredity. Attacks mostly grand mal in type, with gastric aura. Duration, eight years. Past history negative, except epilepsy and dementia. Never went to school on account of convulsions. Physical examination, negative. Died Jan. 25, 1909. Age, eleven years. Cause of death: Pulmonary tuberculosis.

Microscopical. — Heart: Negative. (Lung: Not preserved.) Spleen: Congestion. Trabecular tissue increased. Hyaline in arterial walls. Small tubercle. Liver: Vacuolation of cells about central vein. Lymphocytic infiltration of periportal tissue. Kidney: Negative. Adrenal: Negative.

CASE III. No. 586. Male. Admitted April 1, 1902. Birthplace, Massachusetts. Onset of this series of attacks of epilepsy at forty-four years. Assigned cause, alcohol. Heredity, father epileptic. Attacks grand mal in type. Duration, twenty-four years. Past history of children's diseases and typhoid at twenty years. Had convulsions while a boy at school. These stopped and began at forty-four years. Physical examination: Demented, teeth poor, tongue scarred, apex beat displaced to left. Systolic murmur at apex. Otherwise negative. Died March 26, 1909. Age, sixty-eight years. Clinical diagnosis: Chronic interstitial nephritis with edema of lungs.

Microscopical. — Heart: Negative. (Lung: Not preserved.) Spleen: Small hemorrhages into pulp. Trabecular tissue increased. Hyaline in arterial walls. Liver: Congestion and pigmentation about central vein. Kidney: Chronic interstitial nephritis. Arteriosclerosis.

CASE IV. No. 977. Male. Admitted Feb. 1, 1905. Birthplace, Connecticut. Onset of epilepsy at seventy-three years of age. Assigned cause, old age. Attacks began like sunstroke. Duration, six years. Past history, incomplete. Has taken medicine for heart. Habits, good. Physical examination: Appears demented, nutrition poor, teeth bad. Otherwise negative. While in the hospital, patient had frequent severe convulsions followed by exhaustion. Died March 28, 1909. Age, seventy-nine years. Clinical diagnosis: Chronic interstitial nephritis.

Microscopical. — Heart: Advanced fibrous myocarditis. Spleen: Extreme congestion with small hemorrhages into pulp. Trabecular tissue increased. Hyaline in arterial walls. Liver: Negative. Kidney: Chronic interstitial nephritis with marked arteriosclerosis.

CASE V. No. 1300. Male. Admitted April 22, 1907. Birthplace, Massachusetts. Onset of epilepsy at thirty-four years. Assigned cause, injury. No heredity. Grand mal attacks. Duration twenty-two years. Has had diseases of childhood. Physical examination shows patient somewhat demented, teeth poor, arteries sclerotic. Knee jerks exaggerated. Otherwise negative. Epilepsy followed accident in which patient was hit on the head by a plank and received a severe scalp wound. He was unconscious after the blow. April 5 he began to have frequent seizures which continued until his death, April 8, 1909. Age, fifty-six years. Clinical diagnosis: Status epilepticus.

Microscopical. — Heart: Diffuse fibrous myocarditis. Lung: Healed tuberculosis. Chronic bronchitis. Spleen: Marked congestion. Small hemorrhages. Trabecular tissue increased. Arteries sclerosed, with hyaline in walls. Follicles small and inactive. Pancreas: Negative. Liver: Congested. Kidney: Chronic interstitial nephritis. Arteriosclerosis. Many casts. Adrenal: Negative.

CASE VI. No. 706. Male. Admitted Nov. 17, 1902. Birthplace, Massachusetts. Parents born in Ireland. Onset of epilepsy at eight years. Cause unknown. No heredity. Grand mal and petit mal attacks. Duration thirty-one years. Has had diseases of childhood. Habits good. Physical examination shows patient slightly demented, otherwise negative. Died April 10, 1909. Age thirty-nine years. Clinical diagnosis: Diabetes mellitus.

Microscopical. — Heart: Fibrous myocarditis. Lung: Gelatinous bronchopneumonia. Lymph nodes show tubercles. Spleen: Trabecular tissue increased. Hyaline in arterial walls. Pancreas: Negative. Liver: Slight central necrosis. Kidneys and adrenal: Negative.

CASE VII. No. 1399. Female. Admitted Nov. 16, 1907. Birthplace, Massachusetts. Onset of epilepsy at thirteen years. Cause unknown. Heredity, mother epileptic, father alcoholic. Grand and petit mal attacks. Duration eleven years. Has had diseases of childhood, including scarlet fever at seven years of age, after which she was blind for one month. Physical examination negative. Nov. 18, 1908, examination showed lungs affected. Died April 1, 1909. Age, twenty-four years. Clinical diagnosis: Pulmonary tuberculosis.

Microscopical. — Heart: Negative. Lung: Many large caseous tubercles. Lymph nodes show miliary tubercles. Spleen: Passive congestion. Follicles only slightly active. Hyaline in arterial walls. Intestine: Tuberculous ulcers and tubercles extending through muscular coat. Pancreas: Negative. Liver: Large areas of central congestion and necrosis with vacuolation of liver cells. Kidney: Slight increase in interstitial tissue. A few casts.

CASE VIII. No. 174. Male. Admitted July 25, 1898. Birthplace, Massachusetts. Parents born in Ireland. Onset of epilepsy at thirty years. Assigned cause, alcohol. No heredity. Grand and petit mal attacks. Duration twenty-eight years. First convulsion followed a period of heavy drinking. Suffers from indigestion. Heart irregular. Died April 14, 1909. Age, fifty-six years. Clinical diagnosis: Cardiac paralysis.

Microscopical. — Heart: Slight fibrous myocarditis. Lungs: Some induration. A few small fibrous tubercles. Many large cells filled with golden brown pigment. Lymph nodes contain small tubercles. Spleen: Congested. Tuberculous. Follicles large but rather inactive. Hyaline in arterial walls. Pancreas: Many fat vacuoles. Liver: Congestion about central vein. Areas of focal necrosis. Kidneys: Cortex largely replaced by connected tissue. Many large caseous areas throughout. Fatty capsule studded with tubercles. Arteriosclerosis. Adrenal: Negative. Ureters and bladder: Necrosis of mucosa; surface covered by a necrotic exudate. Infiltration of deep layers by leucocytes.

CASE IX. No. 293. Male. Admitted Aug. 30, 1899. Birthplace, Massachusetts. Onset of epilepsy at seventeen years. Assigned cause, heredity. Mother epileptic and maternal aunt insane. Grand and petit mal attacks. Duration thirty-eight years. Habits temperate. Physical examination shows hips ankylosed at nearly right angle to the body. Said to be due to rheumatism and the result of a fall. Died April 30, 1909. Age, fifty-five years. Clinical diagnosis: Cerebral hemorrhage.

Microscopical. — Heart: Negative. Lung: Negative. Spleen: Markedly congested throughout. Follicles small and inactive. Hyaline in arterial walls. Pancreas: Negative. Liver: Central congestion and pigmentation of liver cells. Periportal tissue infiltrated by lymphocytes. Kidney: Marked congestion throughout. A few sclerotic glomeruli and tubules. A few casts. Adrenals: Negative.

Case X. No. 962. Male. Admitted Dec. 3, 1904. Birthplace, Massachusetts. Father born in England. Onset of epilepsy from earliest childhood. Cause unknown. Grand and petit mal attacks. Duration since birth. No heredity. Eruption of teeth at ten months. Convulsions first noticed at this time. Mental weakness first noticed at thirteen years of age. Physical examination shows patient weakminded. Teeth poor and palate high arched. Head square; otherwise negative. March 29, 1907, examination of lungs shows percussion note higher pitched and less duration over apices of both lungs, most marked in right. Auscultation shows broncho-vesicular breathing, a few fine moist râles, and a musical expiratory note. Died May 6, 1909. Age, twenty-six years. Clinical diagnosis: Pulmonary tuberculosis.

Microscopical. — Heart: Multiple acute abscesses of myocardium and endocardium. Partly organized acute fibrinous exudate on epicardium. Venous thrombosis. Masses of staphylococci at center of abscesses. Lungs: Pleura thickened and covered by an acute fibrinous exudate. Some induration. Chronic bronchitis. Edema. Many small abscesses with masses of staphylococci. Infarction. Spleen: Marked congestion throughout. Follicles small. Multiple abscesses, in the centers of some of which are necrotic blood vessels filled with organisms. Many small groups of large, deeply staining lymphoid cells. Intestine: Small abscesses of submucosa. Pancreas: Negative. Liver: Congested. Multiple abscesses irregularly scattered throughout. Many areas of central and focal necrosis. Kidney: Congested, small multiple abscesses. Adrenal: Marked congestion. Small abscess of cortex.

Case XI. No. 406. Male. Admitted Sept. 29, 1900. Birthplace, Massachusetts. Onset of epilepsy during first year of life. Assigned cause, teething. No heredity. Grand mal attacks. Duration twenty-seven years. Physical examination shows patient feebleminded. Teeth poor. Dorsal scoliosis. Otherwise negative. Feb. 26, 1907, examination of lungs shows vocal fremitus increased over upper part of right lung. Signs present over both front and back. Roughened breathing and musical expiratory note. April 1, 1909. Patient sleeping out of doors. Has gradually failed and is very weak. Died May 10, 1909. Age, twenty-eight years. Clinical diagnosis: Pulmonary tuberculosis.

Microscopical. — Heart: Negative. Lung: Many caseous conglomerate tubercles. Lung congested throughout. Spleen: Acute splenitis. Follicles distinct and active, some contain a small amount of hyaline. Pancreas: Negative. Liver: Marked congestion throughout. Pigmentation of liver cells about central vein. Kidney: Marked congestion. Cloudy swelling of tubular epithelium. Adrenals: Negative.

Case XII. No. 743. Female. Admitted April 3, 1903. Birthplace, Canada. Onset of epilepsy at seven years. Assigned cause, fright and injury. Heredity, mother said to have been nervous. Grand mal and petit mal attacks. Duration fourteen years. Has had ordinary diseases of childhood. On physical examination appears dull mentally. Palate high arched. Heart intermittent. History and symptoms of paraplegia. Left scoliosis of lower dorsal and first lumbar vertebræ. Reflexes exaggerated; sensation diminished. Convulsions frequent. Died May 17, 1909. Age, twenty-two years. Clinical diagnosis: Exhaustion following status epilepticus.

Microscopical. — Heart: Negative. Lung: Intense congestion. Many caseous conglomerate tubercles. Spleen: Acute congestion with numerous small hemorrhages. Follicles distinct and slightly active. Some contain a few endothelial cells. Many plasma cells scattered throughout. Liver: Congestion about the central vein with quite extensive areas of necrosis of liver cells, many of which contain one or more fat vacuoles. An occasional endothelial cell is seen in the sinusoids. Pancreas: Negative. Kidney: Acute degeneration of epithelium lining the convoluted tubules, and small scattered hemorrhages. Adrenal: Intense congestion of medulla.

Case XIII. No. 122. Female. Admitted June 14, 1898. Birthplace, Massachusetts. Onset of epilepsy at fourteen years. Assigned cause, scarlet fever. Heredity, maternal grandfather had "fainting spells." Attacks grand mal in type. Duration forty years. Died May 24, 1909. Age, fifty-three years. Clinical diagnosis: Cerebral hemorrhage due to status epilepticus.

Microscopical. — Heart: Negative. Lung: Many tubercles of varying size. The larger ones are caseous. All are surrounded by considerable connective tissue. Spleen: There is a considerable amount of congestion. The trabecular tissue is increased. The follicles are distinct but inactive. A slight amount of hyaline in the arterial walls. Pancreas: Negative. Liver: There is an increase in periportal connective tissue. Some of the central veins are dilated and their walls thickened. The liver cells throughout contain many fine vacuoles. Kidney: There is some thickening of the capsule and slight focal increase in interstitial tissue. The epithelium of the convoluted tubules shows acute degeneration. Slight arteriosclerosis. Adrenal: Negative.

Case XIV. No. 1172. Male. Admitted Dec. 17, 1898, age thirty-four years. Onset at thirty-one years. Assigned cause, injury while blasting, one year earlier. Attacks grand mal in type, increasing in number and severity, varying from five to twelve each month. On Dec. 7 and 8, 1902, a series of convulsions. Died Dec. 8, 1902. Age, thirty-eight years. Clinical diagnosis: Death during convulsion.

Microscopical. — Heart: Negative. Lungs: Many conglomerate tubercles. Edema. Congestion. Liver: Central congestion, cells granular, and contain many vacuoles. Kidney: Marked congestion. Tubular epithelium swollen and granular.

Case XV. No. 918. Male. Admitted Sept. 16, 1904. Birthplace, Massachusetts. Onset of epilepsy at sixty-six years. No cause assigned. Heredity, mother had several attacks of insanity when young. A sister, brother, and uncle insane. Patient had scarlet fever with slight deafness when a child; some time ago fell from a mast striking on head and was unconscious three or four hours. Three years ago was overcome by gasoline. Had dropsy several years ago. A year ago was burned in an attempt to put out a fire, and has not been well since. Has had spells of shaking for two years. During last three weeks has had three severe fits, one accompanied by a slight shock. Physical examination shows general arteriosclerosis. Gait feeble. Reflexes slightly diminished. Otherwise negative. From Oct. 24 to Oct. 28 had over one hundred convulsions. Died Oct. 28, 1904. Age, sixty-eight years. Clinical diagnosis: Status epilepticus and pneumonia.

Microscopical. — Heart: Slight fibrous myocarditis. Lung: Acute lobar pneumonia, acute bronchitis. Spleen: Acute splenitis. Walls of arteries thickened and contain hyaline. Liver: Central congestion and vacuolation of liver cells. Kidney: Cloudy swelling of tubular epithelium. Many hyaline casts. Arteriosclerosis.

Case XVI. No. 949. Male. Age, fifty-six. Birthplace, Massachusetts. Onset of epilepsy soon after birth. No cause assigned. No heredity. History not remarkable. At sixteen years showed capacity of child of six. Physical examination negative. Nov. 29, 1904. Has three to four convulsions each month. Examina-

tion shows moist râles on front and back of right side, and in left apex. Died Jan. 23, 1905. Clinical diagnosis: Miliary tuberculosis.

Microscopical. — Heart: Chronic fibrous myocarditis. Tubercular pericarditis. Lung: Conglomerate tubercles. Tubercular pneumonia. Spleen: Large caseous tubercles. Congestion. Hyaline in arterial walls. Liver: Miliary and conglomerate tubercles scattered irregularly throughout. Central necrosis of liver cells and vacuolation at periphery of lobule. Intestine: Tubercle on peritoneal surface. Kidney: Chronic diffuse nephritis with hyaline casts.

CASE XVII. No. 952. Male. Admitted Oct. 28, 1903. Birthplace, Massachusetts. Onset of epilepsy at twenty-three years. Occurred every six to twelve days. Attacks grand mal in type, usually at night. Heredity: Parents intemperate. Cousin of the patient epileptic. One other child in the family feeble-minded. Mother died with tuberculosis. Habits always good. Physical examination: Showing systolic murmur at apex of heart. Otherwise negative. Feb. 8, 1905. Rigor with temperature, pain in the chest, and râles over both sides. Breathing rapid. Feb. 10, 1905, cyanotic. Died suddenly. Age, fifty-four years. Clinical diagnosis: Double lobar pneumonia.

Microscopical. — Heart: Fibrous myocarditis. Lung: Acute lobar pneumonia. Acute bronchitis. Spleen: Acute splenitis. Thickened arterial walls. Liver: Congested throughout. Diffuse vacuolation of liver cells. Kidney: Chronic diffuse nephritis. Few casts. Arteriosclerosis. Adrenal: Hemorrhage into medulla.

CASE XVIII. No. 1021. Male. Epilepsy congenital. Heredity, mother irritable and nervous. One brother is in many respects like patient. The entire family have some speech defect. Early development slow. No illnesses. Habits good. Attacks increasing in frequency. Physical examination: Gait feeble. Teeth gone, arteries stiff. Few moist râles over back of both lungs. Pulse, increased tension. Reflexes slow. Otherwise negative. Nov. 4, 1907. Patient put in bed. Temperature and respiration increased. Dullness over lower part of lungs in the back and increased respiratory sounds in the chest. Died Nov. 13, 1906. Age, sixty-five years. Clinical diagnosis: Lobar pneumonia.

Microscopical. — Heart: Negative. Lungs: Thickened pleura. Acute lobar pneumonia. Infarction. Edema: Hemorrhage. Spleen: Congested. Follicles active. There are many phagocytic endothelial cells scattered throughout. Hyaline in arterial walls. Liver: Central congestion. Areas of focal necrosis. Some vacuolation of liver cells. Kidney: Chronic diffuse nephritis. Arteriosclerosis. Few casts. Intestine: Hyperplasia of lymphoid tissue (typhoid).

CASE XIX. No. 1023. Female. Admitted May 5, 1905. Birthplace, Massachusetts. Onset of epilepsy at seventy-two years. Assigned cause, senility. Heredity, none known. One brother insane after sixty years of age. Duration, four years. History, negative. Said to be of nervous temperament. At first attack was unconscious some hours. Followed by paresis of tongue, throat and lower extremities. Convulsions frequent, but irregular. Has no memory. Physical examination: Puffiness of ankles and under eyes. Otherwise negative. Nov. 22, 1905. Seizures frequent, especially at night. Has had elevated temperature and stertorous breathing, grown weak. Died Nov. 22, 1905. Age, seventy-six years. Clinical diagnosis: Arteriosclerosis. Epilepsy.

Microscopical.—Heart: Chronic fibrous myocarditis. Lung: Induration. Bronchopneumonia. Acute bronchitis. Marked congestion. Many large cells contain golden brown pigments. Bronchial lymph node contains many small tubercles. Spleen: Marked congestion. Arteriosclerosis. Hyaline in arterial walls, and in some of the follicles. Liver: Central congestion. Cells small. Kidney: Chronic interstitial nephritis. Few casts. Arteriosclerosis.

CASE XX. No. 1071. Male. Admitted April 11, 1906. Onset of epilepsy at about thirty-six years. Assigned cause, sunstroke during the Civil War. Heredity: Mother died at sixty, insane. One sister insane since girlhood. One sister died of paralysis. A nephew is said to be "peculiar." Two children, both have nervous trouble. Attacks of grand mal type. Have increased in frequency, both night and day. History of having taken alcoholics moderately all his life. Had typhoid before the war Examination shows stiffened arteries, otherwise negative. Died June 20, 1907. Age, sixty-six years. Clinical diagnosis: Bronchopneumonia.

Microscopical.—Heart: Fibrous myocarditis. Lungs: Acute lobar pneumonia, acute pleuritis. Spleen: Congested. Hyaline in follicles and in walls of arteries. Arteriosclerosis. Pancreas: Chronic interstitial pancreatitis. Arteriosclerosis. Kidney: Chronic diffuse nephritis. Arteriosclerosis. A few casts.

CASE XXI. No. 1076. Female. Admitted June 22, 1906. Onset of epilepsy at forty years. No known cause. No heredity. Family and personal history good. Habits good. Physical examination: Negative. July 8, 1906, râles over left lower back. Some edema of ankles. Died July 10, 1906. Age, forty-five years. Clinical diagnosis: Pneumonia and epileptic insanity.

Microscopical. — Heart: Negative. Lungs: Acute lobar pneumonia. Liver: Central necrosis and congestion. Portal cirrhosis. Kidney: Negative.

CASE XXII. No. 1104. Male. Admitted Oct. 15, 1901. Onset of epilepsy at five years. Assigned cause, heredity. One brother epileptic. Mother died at thirty years, of consumption; father at seventy years, from cancer: Attacks frequent. Grand mal and petit mal. Personal history not obtained. Physical examination: Unsatisfactory, owing to patient's condition, but was negative as far as made. Oct. 27, 1906, patient found dead in chair, larynx filled with tobacco, probably inspired during a convulsion. Age, forty-five years.

Microscopical.—Heart: Negative. Lungs: Negative. Spleen: Capsule thickened. Trabeculæ prominent. Acute splenitis. Some thickening of arterial walls. Liver: Some central congestion. Cells have a peculiar granular appearance. Some increase in periportal connective tissue. Walls of hepatic arteries slightly thickened. Kidney: Marked congestion throughout. Focal increase of connective tissue representing a few tubules and sclerotic glomeruli.

CASE XXIII. No. 1105. Male. Admitted Feb. 27, 1905. Birthplace, Massachusetts. Onset of epilepsy at seventy years. Assigned cause, senility. No heredity known. Family history not obtained. Patient has never been sick, was hard working, temperate man, but nervous and irritable. Attacks of grand mal type, increasing in frequency. Physical examination: Movements feeble, eyelids edematous; teeth gone; temperature 100° on admission. A few coarse râles on both sides of sternum. Faint systolic murmur at apex of heart. Arteries thickened, otherwise negative. Died Oct. 31, 1906. Age, eighty-five years. Clinical diagnosis: Pneumonia.

Microscopical. — Heart: Advanced diffuse fibrous myocarditis. Lung: Acute lobar pneumonia. Chronic bronchitis. Arteriosclerosis. Spleen: Acute splenitis. Arteriosclerosis. Hyaline in arterial walls. Liver: Slight increase in periportal tissue. Congestion and pigmentation of cells about the central vein. Kidney:

Chronic diffuse nephritis. Many hyaline casts. Arteriosclerosis.

Case XXIV. No. 1124. Male. Admitted Jan. 15, 1906. Birthplace, Maine. Onset at seven years. Assigned cause, infantile hemiplegia. Father died at forty years, cause unknown. Mother died at thirty-eight years, of tuberculosis. No family neurosis or insanity known. Patient well until had whooping cough at seven years. Had attacks from that time until thirty years of age, then no more until forty-five. Habits good. Physical examination: Quite helpless owing to hemiplegia. Left lower extremities smaller than right, temperature 101° on admission. Teeth poor. Otherwise negative. Died Dec. 28, 1906. Age, fifty-two years. Clinical diagnosis: Arteriosclerosis. Epilepsy.

Microscopical. — Heart: Negative. Lung: Acute bronchitis. Slight bronchopneumonia. Edema. Spleen: Marked congestion throughout. Many endothelial cells in pulp contain golden yellow pigment. Arterial walls much thickened and contain large amount of hyaline. Follicles inactive. Liver: Negative. Kidney: Chronic interstitial nephritis. Advanced arteriosclerosis.

Case XXV. 1162. Female. Admitted April 2, 1907. Onset at nine years. No cause known. No heredity. Father and mother living and well. Father a moderate drinker. Patient is the third of ten children. All others well. Had a convulsion at eighteen months, but no more until nine years old. Attacks growing more frequent; grand mal type; mind recently affected. Physical examination; poorly developed and nourished. Teeth poor. Loud, coarse râles all over chest with increased heart sounds, no dullness. Otherwise negative. April 8, 1907, frequent convulsions and did not regain consciousness. Died April 13, 1907. Age, fourteen years. Clinical diagnosis, status epilepticus.

Microscopical. — Heart: No section. Lung: Edema, congestion. Spleen: Marked congestion throughout. Follicles slightly active. Hyaline in arterial walls. Pancreas: Negative. Liver: No section. Kidney: Cloudy swelling of epithelium of convoluted tubules. Few casts. Adrenal: Diffuse vacuolation of cortical cells.

Case XXVI. No. 1166. Female. Admitted April 23, 1907. Onset of epilepsy at forty-five years. Assigned cause, a blow on the head. This injury was questioned as being due to an epileptic seizure. Father dead from unknown cause. Mother died at seventy-five years, from shock. Ten children, all healthy except one sister who is insane. No other heredity or neurosis known. Attacks affect right side. Habits good. Physical examination: Fairly developed and nourished. Teeth gone. Breath sounds harsh over right; harsh blowing murmur at apex of heart. Abdomen negative. Temperature 102.2. Patient practically unconscious. Died April 25, 1907. Age, sixty-one years. Clinical diagnosis: Bronchopneumonia.

Microscopical. — Heart: Negative. Lung: Acute lobar pneumonia. Edema. Spleen: Markedly congested. Follicles small and but slightly active. Arterial walls contain hyaline. Liver: Central congestion. Vacuolation of liver cells at periphery of lobule. Kidney: Capsule thickened. Chronic diffuse nephritis. Many hyaline casts. Some arteriosclerosis.

Case XXVII. No. 1216. Female. Admitted Jan. 20, 1903. Birthplace, Scotland. Onset of epilepsy at thirteen years of age. No known cause. No heredity. With exception of measles always well. Bright in school. Seizures began without warning. Physical examination shows patient fairly developed but poorly nourished. There is a small dull area in the left subclavicular region. Knee jerks slightly diminished. Otherwise negative. Nov. 25, 1907, cellulitis developed on back of right hand; extended up arm to axilla. Cultures show streptococci. Died Dec. 3, 1907. Age, fifty-five years. Clinical diagnosis: Speticemia.

Microscopical. — Heart: Negative. Lung: Pleura thickened. Acute lobar pneumonia. Acute bronchitis. Many diplococci both intra- and extra-cellular. Spleen: Acute congestion. Hyaline in arterial walls and in some follicles. Large numbers of plasma cells scattered throughout. Liver: Marked central congestion with some atrophy and pigmentation of liver cells. Kidney: Chronic diffuse nephritis and slight arteriosclerosis. Adrenal: There are many small groups of lymphoid cells irregularly scattered throughout. Many of the cells contain vacuoles.

Case XXVIII. No. 1217. Female. Admitted Dec. 12, 1906. Onset of epilepsy at thirteen months. No cause known. No heredity. Father a moderate drinker never to intoxication. Attacks grand and petit mal in type. Patient never went to school but was considered bright until nine years of age. Was unable to learn household duties. Is poorly nourished; has hare-lip and is defective in speech and gait. Lateral scoliosis. Pulse weak, heart sounds indistinct but no murmurs. Dec. 4, 5, 1907, has had repeated convulsions, severe and constant, cyanosed, pulse weak and rapid. Died Dec. 6, 1907. Age fifteen years. Clinical diagnosis: Bronchopneumonia.

Microscopical. — Heart: No section. Lung: Pleura thickened. Acute bronchopneumonia. Acute and chronic bronchitis. Spleen: Increase in trabecular tissue. Follicles only slightly active. Some hyaline in arterial walls. Liver: Some increase of connective tissue about larger veins both portal and hepatic. Bile capillaries dilated, especially at center of lobule. Cells small and contain a considerable number of small fat vacuoles. Kidneys: Negative. Adrenal: Negative.

Case XXIX. No. 1227. Female. Admitted June 17, 1904. Onset of epilepsy second day after birth. Mother and father living and well. Father deaf and of low grade of intelligence. No intemperance. Patient has congenital hydrocephalus. Fontanelles closed at fourth year. Never able to go to school. Attacks have increased in frequency. Physical examination: Gait unsteady and halting. Stooping figure. Teeth poor. Pupils unequal, the right being a trifle larger. Heart has harsh blowing murmur at apex transmitted to the axilla. Same sound over aortic area at base. No thrill. Died Jan. 12, 1908. Age, thirty-three years. Clinical diagnosis: Bronochopneumonia.

Microscopical. — Heart: Negative. Lung: Many large caseous tubercles. Bronchopneumonia. Chronic bronchitis. Spleen: Acute splenitis. Trabecular tissue increased. Some hyaline in arterial walls. Follicles only slightly active. Liver: Marked dilatation of capillaries about the central vein with beginning necrosis of liver cells. Kidney: Chronic interstitial nephritis. Some arteriosclerosis.

Case XXX. No. 1285. Male. Admitted March 27, 1906. Onset of epilepsy at five years. Father living and well. Mother living. Has had pulmonary tuberculosis for ten years. Patient strong and well until five years when he had a series of convulsions and was unconscious for several days. Was unable to walk for several months and had to learn to talk again. Has never been bright since attacks began. Habits good. Has been unable to walk for past six years. Physical examination: Lower extremities deformed. Thighs bowed outward and forward. Left over one one inch shorter than right. Left knee thickened. Otherwise negative. Patient described as a low grade idiot with paralyzed limbs. No appreciation of most questions, but whines and cries most of the time.

Patient had a series of severe convulsions lasting over twenty-four hours, after which consciousness was never regained. Died Oct. 28, 1908. Age, eighteen years. Clinical diagnosis: Status epilepticus.

Microscopical. — Heart: Negative. Lung: Pleura thickened; edema. Spleen: Intensely congested. Many small hemorrhages into pulp. Follicles small and inactive. Pancreas: Negative. Liver: Congested throughout. Kidney: Chronic diffuse nephritis. Adrenal: Negative.

CASE XXXI. No. 1304. Male. Admitted Dec. 10, 1908. Birthplace, Germany. Onset of epilepsy at thirty-four years. Assigned cause, alcohol. No heredity. Patient is said to have nervous temperament. History of having fallen from a tree when a boy. Duration of attacks ten years, increasing in frequency; worst convulsions when full moon is shining. Demented, poorly nourished and developed. Examination impossible owing to condition of patient. December, 1908, patient has fallen from the bed several times at night with convulsions. Died Feb. 21, 1909. Age, forty-four years. Clinical diagnosis: Status epilepticus.

Microscopical. — Heart: Negative. Lung: Acute bronochopneumonia. Acute bronchitis. Many intracellular diplococci. Spleen: Much congested. Increase in trabecular tissue. Arterial walls thickened and contain considerable hyaline. Most of the follicles small and only slightly active. Liver: Intense congestion throughout. The liver cells vary in size and many have two nuclei. Pancreas: Negative. Kidney: Chronic diffuse nephritis. Some arteriosclerosis. Adrenal: Negative.

CASE XXXII. No. 110. Female. Onset of epilepsy at thirteen years. Attacks every two months, increasing in frequency. Family history, negative. Has had children's diseases. Never been able to play without shortness of breath. Scarlet fever at five years, with discharge from left ear, which has continued. Admitted to hospital Aug. 10, 1903, with temperature, headache and pain in back. Left side seems weaker than right on trying to walk. Physical examination shows cyanosis, delirium and general hyperesthesia. Ptosis of left lid; slight paresis of left side of face. Tongue protruded straight. Dullness in lower right back with a few fine moist râles. Heart sounds rapid and weak. Pulse scarcely perceptible at wrist. Ankle clonus on left. Died Aug. 11, 1903. Age, seventeen years. Clinical diagnosis: Typhoid fever.

Microscopical. — Heart: Slight chronic endocarditis and chronic focal myocarditis. Lungs: Pleura slightly thickened. Chronic congestion of the lungs. Many endothelial cells contain golden brown pigment. Spleen: Acute splenitis with intense acute congestion. Many phagocytic endothelial cells irregularly scattered throughout. Follicles rather indistinct. Some appear inactive. Pancreas: Negative. Liver: There is considerable central congestion with atrophy and necrosis of the liver cells. The sinusoids contain many phagocytic endothelial cells and groups of polymorphonuclear leucocytes. Kidney: Acute parenchymatous degeneration. Adrenal: Negative.

CASE XXXIII. No. 5167. Worcester. Female. Admitted July 21, 1900. Birthplace, Massachusetts. Onset of epilepsy at eleven months. Between age of seven and fifteen years had no attacks. Duration, fifty-five years. History of father being intemperate. No direct heredity known. Habits good. Physical examination shows patient poorly developed and nourished; appears demented, with scoliosis. Otherwise negative. June, 1901, patient began running an evening temperature; no cough. Gradually failed and died Aug. 20, 1901. Age, fifty-six years. Cause of death: General miliary tuberculosis.

Microscopical. — Heart: Focal fibrous myocarditis. Lungs: Tuberculous pleuritis. Pulmonary tuberculosis. Spleen: Congestion throughout with small hemorrhages. Caseating tubercules. A few small abscesses. Follicles distinct, inactive. Liver: Miliary tuberculosis. Diffuse vacuolation of liver cells. Central pigmentation. Kidney: Slight diffuse nephritis. A few conglomerate tubercles. Arteriosclerosis.

CASE XXXIV. No. 22170. Worcester. Female. Admitted May 23, 1902. Birthplace, Massachusetts. Father and mother born in Ireland. Onset of epilepsy at thirteen years. Duration, fifteen years. Patient was bitten by a dog a few days before first attack. Family history: Father asthmatic. No direct heredity. Attended school until fifteen years of age. Habits temperate. Attacks increased in frequency. Patient demented. Physical examination: Negative. Died July 11, 1904. Age, twenty-eight years. Cause of death, pulmonary edema.

Microscopical. — Heart: Negative. Lung: Negative. Spleen: Considerable trabecular increase. Follicles distinct. Small hemorrhagic areas. Arteries slightly hyaline. Pancreas: A few small hemorrhages. Liver: Moderate congestion. Thickening of walls of some central veins and distention with blood. Kidney: Congestion throughout. Cloudy swelling. Arteries good.

CASE XXXV. No. 23049. Worcester. Male. Admitted Oct. 26, 1903. Birthplace, Massachusetts. Father and mother born in Sweden. Onset of epilepsy at sixteen years. Duration of epilepsy, nine years. Had pneumonia and scarlet fever in childhood. Family history negative. No heredity known. Memory failed at twelve years. At fourteen had staring spells when patient would "lose himself." Habits temperate. Physical examination, negative. Died June 17, 1904. Age, twenty-five years. Cause of death, status epilepticus and beginning pneumonia.

Microscopical: — Heart: Negative. Lung: Congestion and edema. Beginning pneumonia. Some large cells contain golden brown pigment. Spleen: Increase in trabecular tissue. Intense congestion. Follicles distinct, but inactive. A few small hemorrhages. Pancreas: Negative. Liver: Congestion. Diffuse cell vacuolation. Kidney: Slight diffuse nephritis. Slight arteriosclerosis.

CASE XXXVI. No. 20532. Worcester. Male. Admitted August, 1899. Birthplace, Massachusetts. Onset of epilepsy at thirty-four years. At six years fell from swing hitting head. At twelve years had sunstroke and was out of his head for two days. After that was dull. Family history, negative. Duration, twenty-two years. Habits, good. Physical examination, double inguinal hernia, knee jerks diminished on the right; the left are hardly perceptible. Radial pulse weak. Lungs and abdomen negative. Died July 30, 1905. Age, sixty-five years. Cause of death, epileptic convulsion.

Microscopical. — Heart: Brown pigmentation of muscle cells. Lung: Thickened pleura. Congestion, induration and areas of infiltration with lymphoid cells. Spleen: Slight increase in trabecular tissue. Congestion. Follicles distinct and slightly active. Many eosinophiles. Arteries slightly hyaline. Pancreas: Negative. Liver: Central congestion and pigmentation. Several small hemorrhages. Kidney: Slight diffuse nephritis. Hyaline casts.

CASE XXXVII. No. 21527. Worcester. Female. Admitted April 22, 1901. Father and mother born in Germany. Onset of epilepsy at six months. Duration of epilepsy, seventeen years. Family history, negative. No heredity known. Patient has no education. Habits temperate. Physical examination: Teeth poor, muscu-

lar power impaired on right side with exaggerated reflexes. First heart sounds rough with accentuation of second pulmonic. Otherwise negative. Died June 3, 1901. Age, eighteen years. Cause of death, status epilepticus.

Microscopical. — Heart: Negative. Lung: Congestion and edema. Spleen: Congestion. Follicles distinct and slightly active. Many plasma cells. Arteriosclerosis and hyaline arteries. Liver: Congestion. Some vacuolation of liver cells. Kidney: Negative.

Case XXXVIII. Worcester. No. 23944. Male. Admitted March 4, 1905. Birthplace, Hungary. Onset of epilepsy at thirty-eight years. Duration one year. Mother had been bedridden for seven years. Habits: Alcohol and tobacco to excess. No direct heredity known. Physical examination: Well developed, poorly nourished. Gait unsteady. All phalangeal joints ankylosed in some degree. Slight enlargement of inguinal glands. Knee jerks increased. Otherwise negative. Died March 29, 1905. Age, thirty-nine years. Cause of death, status epilepticus.

Microscopical. — Heart: No section. Lung: Lobar pneumonia. Venous thrombosis. Fibrosis of bronchial lymph nodes. Spleen. Increase in trabecular tissue. Many cells contain brown pigment. Follicles distinct, but inactive. Pancreas: Negative. Liver: Central congestion. Slight increase in periportal tissue. Focal necrosis with infiltration by lymphocytes. Vacuolation of peripheral cells. Kidney: Cloudy swelling.

Case XXXIX. No. 6780. Westboro. Male. Admitted Jan. 13, 1906. Birthplace, New York. Father and mother born in England. Onset at thirty-five years of age. Duration, fourteen years. Family history: Mother died of paralysis at seventy-one years. Father a moderate drinker. Patient had rheumatism at fifteen years. The attacks were called fainting spells and occurred at intervals of four weeks with periods of unconsciousness lasting from a few minutes to one-half hour. There was no aura. Patient did not use alcohol. Physical examination: Teeth poor. Area of heart dullness increased with presystolic murmur at apex. Intermits every fifth beat. Radials hard and slightly beady. Urine negative. Died Nov. 21, 1907. Age, forty-nine years. Cause of death: General anasarca with mitral stenosis.

Microscopical. — Heart: Negative. Aorta: large groups of lymphocytes. Lungs: Congestion; early bronchopneumonia. Spleen: Congestion. Follicles distinct, but rather inactive. Many contain groups of phagocytic endothelial cells filled with nuclear detritus. Many polymorphonuclears are scattered throughout. Pancreas: Negative. Liver: Congestion. Periportal tissue is infiltrated with lymphoid cells. Some are seen in the sinusoids with polymorphonuclears. Kidney: Sclerosis of a few glomeruli and tubules. Arteries good.

Case XL. Westboro. No. 6089. Male. Admitted July 27, 1904. Birthplace, England. Onset of epilepsy at eight years. Duration seventeen years. Family history: Paternal grandmother said to have been hysterical. No direct heredity known. Patient had spinal trouble at three months. Did not walk until three years of age. At fourteen years the convulsions became very severe but with longer intervals. During hospital residence had seizures about one a week. Habits good. Had ravenous appetite. Physical examination: Negative except increased reflexes with clonus, Nov. 5, 1908. Fall from trapeze fractured skull and injured cervical and dorsal cord. Followed by death. Age, twenty-five years.

Microscopical. — Heart: Negative. Lungs: Bronchitis and bronchopneumonia. Spleen: Follicles distinct and active. Arteries slightly hyaline. Liver: Negative. Kidney: Negative. Adrenals: Negative.

Case XLI. No. 1124. Male. Admitted Jan. 1, 1906. Birthplace, Massachusetts. Onset of epilepsy at seven years of age. Duration, twenty-two years. Assigned cause, sunstroke. Predisposing cause, heredity. Attacks grand mal in type. Father intemperate. No history obtainable from the patient. Physical examination: Patient has shuffling gait and appears idiotic. Mentally dull. Physical condition good. Teeth poor. Chest contracted. Paresis of right side. Reflexes on right somewhat increased. April 22, 1909. After examination of patient, diagnosis of pulmonary tuberculosis made. Died July 12, 1909. Age, twenty-nine years.

Microscopical. — Heart: Negative. Lungs: Thickened pleura. Extensive fibrosis. Acute bronchitis and bronchopneumonia. Numerous acute abscesses. Spleen: Follicles large, distinct and active. Large numbers of polymorphonuclear and plasma cells are seen. Pancreas: Negative. Liver: Negative. Kidneys: An occasional glomerulus and tubule sclerosed. Adrenal: Negative. Aorta: Small foci of lymphoid infiltration beneath the intima.

Case XLII. No. 702. Male. Admitted Nov. 8, 1902. Birthplace, Maine. Onset of epilepsy at about forty-seven years of age. Duration, sixteen years. Assigned cause, injury to head from fall. Attacks grand mal in type. Physical examination: Patient appears feeble-minded. Teeth are nearly all gone. Heart hypertrophied. Aortic sound accentuated. Otherwise negative. Patient died July 14, 1909. Age, sixty-three years. Cause of death: Valvular heart lesion with general anasarca.

Microscopical. — Heart: The muscle fibers appear much hypertrophied. Lung: Chronic bronchitis, venous thrombosis and hemorrhagic infarction. Spleen: Intense passive congestion. Diffuse increase in connective tissue of stroma. Hyaline arteries. Follicles distinct and slightly active. Pancreas: Negative. Liver: Central congestion and necrosis. Kidney: Diffuse nephritis, edema, arteriosclerosis. Adrenal: Marked passive congestion.

Case XLIII. No. 1748. Male. Admitted July 7, 1909. Birthplace, Massachusetts. Onset of epilepsy in early childhood. Father and mother said to be peculiar and family called sickly. One brother died with epilepsy. Has had a long residence in town farm. Habits good. Talks with difficulty. Confined to bed for two months prior to death on July 14, 1909. Age, sixty years. Cause of death: Cerebral softening.

Microscopical. — Heart: Moderate chronic fibrous myocarditis. Lung: Congestion and bronchopneumonia. Spleen: Capsule thickened and trabecular tissue increased. Marked congestion with many small hemorrhages. Follicles distinct but inactive. Pancreas: Slight chronic fibrous pancreatitis. Liver: Extensive central necrosis with diffuse vacuolation of many of the remaining liver cells. Kidney: Chronic diffuse nephritis and some arteriosclerosis. Adrenal: The cortical portion only remains and many of the cells are vacuolated. There is some infiltration with lymphocytes.

Case XLIV. No. 180. Female. Admitted July 28, 1898. Birthplace, Massachusetts. Onset of epilepsy at twelve years. Duration seventeen years. Assigned cause of epilepsy, heredity. Had chorea at seven and one-half years. Attacks increased in frequency. Mother had fainting spells and was called " nervous." Patient dull and stupid. Physical examination: Negative on admission. Died Aug. 17, 1909. Age, twenty-nine years. Cause of death: Acute dilatation of stomach.

Microscopical. — Heart: Negative. Aorta: Small atheromatous patches. Lung: Thickened pleura with fibrinous purulent exudate. Many bronchiectatic abscesses. Spleen: Congested. Follicles distinct but inactive. Large numbers of plasma cells are seen. Liver: The sinusoids about the central vein are distended with red blood corpuscles. Kidney: Congestion and edema are present. Adrenal. Negative.

CASE XLV. No. 1753. Male. Admitted July 14, 1909. Birthplace, Massachusetts. Onset of epilepsy at nine months. Duration thirteen years. Attended school until eight years of age. No cause for epilepsy assigned. Paternal grandmother has history of fainting spells and at one time paralysis for three months. No convulsions. Patient's great-grandfather died of tuberculosis. Eruption of patient's teeth at nine months, also whooping cough. Physical examination: Patient dull and feeble-minded. Not well nourished otherwise negative. Attacks grand mal in type. Head affected first and at times slight paralysis followed the attack. No aura. Died Sept. 16, 1909. Age, fourteen years. Cause of death: Bronchopneumonia.

Microscopical. — Heart: Negative. Lungs: Thickened pleura, marked congestion. Acute bronchopneumonia. Many bacteria present (cocci). Spleen: Congestion considerable with small hemorrhages. Acute secondary splenitis. Follicles distinct and active. Phagocytic cells in follicles. Arteries negative. Liver: Some central congestions with beginning cell necrosis. Kidney: Cloudy swelling of epithelieum of the convoluted tubules. Adrenals: Negative. Aorta: Negative.

CASE XLVI. No. 636. Female. Admitted June 5, 1902. Birthplace, Massachusetts. Onset of epilepsy at fifteen years of age. Duration forty-two years. Assigned cause, fracture of skull due to accident. Five to twenty attacks monthly, grand mal in type. Past history and family history negative. Physical examination shows patient demented and insane. Circulation and nutrition poor. Teeth poor. Patellar reflex accelerated. Chest and abdomen negative. Died Sept. 20, 1909. Age, fifty-seven years. Cause of death: Epilepsy.

Microscopical. — Heart: Negative. Lung: Congestion is marked throughout. There are a few healed tubercles about the root of the lung and a beginning bronchopneumonia. Many endothelial cells contain masses of golden brown pigment. Spleen: There is considerable congestion and large number of plasma cells are present. The follicles are distinct and active. The arterial walls are thickened. Liver: The cells show slight diffuse vacuolation. Pancreas: There are many large vacuoles each representing several acini. Kidneys: Chronic diffuse nephritis. Arteries sclerotic. Adrenals: The cells contain minute vacuoles. Aorta: Large atheromatous areas in the intima.

CASE XLVII. No. 973. Female. Admitted Jan. 27, 1905. Birthplace, Canada. Onset of epilepsy at eight years of age. Duration twenty-eight years. Cause unknown. No heredity known. Father died at twenty-nine years of age of asthma, mother and brother living and well. Past history, negative. Attacks seven to eight weekly, grand mal in type. Progressive failure of mental condition. Physical examination: Deaf, somewhat feeble-minded. Face asymmetrical. Teeth poor. Chicken breast. Patellar reflex slightly accentuated. Chest and abdomen negative. Sept. 2, 1909, began to show renal symptoms. Failed rapidly and died Sept. 26, 1909. Age, thirty-six years. Cause of death: Chronic nephritis and acute pericarditis.

Microscopical. — Heart: Acute pericarditis with fibrinous exudate. Lung: Focal pleuritis. There appears to be a slight induration of the alveolar walls throughout. Spleen: The capsule is thickened with an increase in trabecular tissue. Arteries sclerotic and slightly hyaline. Pancreas: Slight chronic pancreatitis. Liver: Central congestion throughout and vacuolation of peripheral cells of lobules just beneath the capsule. Kidneys: Thickened capsule. Advanced chronic diffuse nephritis. Arteriosclerosis. Hyaline casts. Adrenal: Negative. Aorta: Marked atheroma of intima.

CASE XLVIII. No. 1247. Male. Admitted Nov. 6, 1906. Birthplace, Massachusetts. Onset of epilepsy at seven months of age. Duration seventeen years. Cause of epilepsy unknown. Partial right hemiplegia said to have followed convulsion. Family history, mother subject to migraine. Mother's mother, sister and brother died with tuberculosis. Father's mother died of "softening of the brain." A paternal cousin died with convulsions. Patient the youngest of eight children, all others living and well. Patient had violent headaches. Attacks confined mainly to paralyzed (right) side. Attacks followed by dull period, and speech interfered with. At three years patient had night terrors and enuresis. Indigestion during childhood. Learned to talk and walk at two years. Attacks three to four weekly, grand mal in type. Right arm and leg affected first. Cries out that attack is coming on. Physical examination shows patient demented with right hemiplegia, otherwise negative. Muscular development good. Died Oct. 1, 1909. Age eighteen years. Cause of death: Epilepsy.

Microscopical. — Heart: Negative. Lungs: Acute pleuritis (diplococcus). Thickened pleura. General congestion of lung. Multiple abscesses (staphylococcus, streptococcus) (bronchiectatic). Spleen: Congested. Follicles distinct and active. Arteries negative. Pancreas: Negative. Liver: Slight congestion throughout. Some of the central veins are dilated and their walls thickened. Kidneys: Cloudy swelling of tubular epithelium. Arteries negative. Adrenals: Occasional groups of lymphoid cells in the medullary portion. Aorta: Atheromatous patches in the intima.

CASE XLVIX. No. 1098. Male. Admitted Nov. 3, 1905. Birthplace, Rhode Island. Father and mother born in England. Onset at two years of age. Duration nineteen years. Assigned cause of epilepsy, "Premature growth of frontal bone." No heredity known. (Mother's brother and father's aunt died of tuberculosis.) Mother mildly hysterical before patient's birth. Eruption of teeth at fourteen months. Patient is mentally feeble, cannot talk. Head asymmetrical. Teeth poor. Physical examination otherwise negative. Attacks grand mal in type. Died Oct. 9, 1909. Age, twenty years. Cause of death: Status epilepticus.

Microscopical. — Heart: Negative. Lung: Slight congestion and edema, acute bronchitis and bronchopneumonia. Spleen: Congestion throughout. Follicles small and inactive. Secondary acute splenitis. Pancreas: Negative. Liver: Central congestion. Focal necrosis with lymphoid infiltration. Kidney: Slight chronic diffuse nephritis. Aorta: Small atheromatous patches on the intima.

CASE L. No. 1103. Male. Admitted Nov. 17, 1904. Birthplace, New Brunswick. Onset at twelve years of age. Duration eleven years. Assigned cause, excessive use of cigarettes. Heredity. Maternal uncle paralyzed. Mother had indigestion and migraine, one brother had rheumatism, one brother died with lung trouble. Eruption of teeth at nine months of age. Walked at twelve months. First attack when aroused in early morning from sound sleep. This has persisted. No aura. Attacks two to twenty-one monthly, grand mal and petit mal in type. Patient feeble-minded from epileptic attacks. Physical ex-

amination: Negative. Died Oct. 12, 1909. Age, twenty-three. Cause of death: Lobar pneumonia.

Microscopical. — Heart: Negative. Lung: Thickened pleura, acute bronchitis and lobar pneumonia. Excessive fibrin formation and many organisms (diplococcus lanceolatus). Some edema. Spleen: Marked congestion. Follicles distinct and active, some contain hyaline. Pancreas: Negative. Liver: Dilatation of central veins surrounding congestion. Kidneys: Slight chronic interstitial nephritis. Adrenal: Negative. Aorta: Atheromatous patches on the intima.

GENERAL STATISTICS.

1. Sex: Male, 33; female, 17.

2. Age at death: Minimum, 11 years; maximum, 85 years; average, 43 years.

3. Years of hospital residence: Minimum, 2 days; maximum, 10 years 9 months; average, 3 years.

4. Assigned causes: Heredity, 2 (4%) cases mother epileptic, 1 (2%) case father epileptic, 7 (14%) cases father alcoholic, 4 (8%) cases insanity in some branch of family, 15 (30%) cases of nervous and mental symptoms in family, 2 (4%) cases asthma in paternal parent, 2 (4%) cases tuberculous maternal parent.

Other causes: 9 (18%) cases of injury to patient, 4 (8%) cases patient alcoholic, 3 (6%) cases at time of teething, 3 (6%) cases assigned to senility, 3 (6%) cases assigned to scarlet fever, 2 (4%) cases assigned to sunstroke, 1 (2%) excessive use of cigarettes, 1 (2%) congential hydrocephalus, 1 (2%) premature growth of frontal bone.

5. Age at onset: By decades, from 1 to 10 years, 23 cases (46%); 10 to 20 years, 10 cases (20%); 20 to 30 years, 1 case (2%); 30 to 40 years, 8 cases (16%); 40 to 50 years, 3 cases (6%); 50 to 60 years, 0 cases; 60 to 70 years, 2 cases (4%); 70 to 80 years, 3 cases (6%).

In periods of five years: from 1 to 5 years, 13 cases (26%); 5 to 10 years, 10 cases (20%); 10 to 15 years, 6 cases (12%); 15 to 20 years, 4 cases (8%); 20 to 25 years, 1 case (2%); 25 to 30 years, 0 cases; 30 to 35 years, 5 cases (10%); 35 to 40 years, 3 cases (6%); 40 to 45 years, 1 case (2%); 45 to 50 years, 2 cases (4%); 50 to 55 years, 0 cases; 55 to 60 years, 0 cases; 60 to 65 years, 1 case (2%); 65 to 70 years, 1 case (2%); 70 to 75 years, 3 cases (6%).

In periods of seven years: from 1 to 8 years, 19 cases (38%); 8 to 15 years, 10 cases (20%); 15 to 22 years, 4 cases (8%); 22 to 29 years, 1 case (2%); 29 to 36 years, 6 cases (12%); 36 to 43 years, 3 cases (6%); 43 to 50 years, 2 cases (4%); 50 to 57 years, 0 cases; 57 to 64 years, 1 case (2%); 64 to 71 years, 2 cases (4%); 71 to 78 years, 2 cases (4%).

6. Duration of epilepsy: Longest period, 65 years; shortest period, 1 year; average duration, 22.74 years.

7. Lesions of trunk organs: Heart: 32 (64%) cases negative, 18 (36%) cases show lesions, 13 (26%) cases chronic fibrous myocarditis, 1 (2%) case multiple abscesses with pericarditis, 1 (2%) case endocarditis, 1 (2%) case brown atrophy, 1 (2%) case hypertrophy of muscle cells, 1 (2%) case acute fibrous pericarditis. (With one exception the subject was over 50 years of age.) Lung: 7 (14%) cases negative, 43 (86%) cases show lesions, 9 (18%) cases active tuberculosis, 5 (10%) cases healed tuberculosis or tuberculosis lymphnodes, 21 (42%) cases acute pneumonia, 10 (20%) cases edema, 4 (8%) cases bronchiectatic abscess, 4 (8%) cases chronic bronchitis, chronic pleuritis, infarct and slight induration. Spleen: 2 (4%) cases negative, 48 (96%) cases show lesions, 3 (6%) cases tuberculosis, 62 (31%) cases hyaline arteries, 12 (24%) cases arteriosclerosis, 16 (32%) cases increase of trabecular tissue, 21 (42%) cases follicles inactive or only slight activity, 34 (68%) cases varying degrees of congestion, 9 (18%) cases small hemorrhages, 8 (16%) cases secondary acute splenitis, usually with acute pneumonia, 5 (10%) cases hyaline follicles, 4 (8%) cases phagocytic cells in follicles. Pancreas: 43 (86%) cases negative, 7 (14%) cases show lesions, 2 (4%) cases fat vacuolation, 3 (6%) cases chronic fibrous pancreatitis, 1 (2%) cases interstitial hemorrhage, 1 (2%) case lymphoid infiltration. Liver: 4 (8%) cases negative, 46 (92%) cases show lesions, 1 (2%) case carcinoma, 20 (40%) cases fat vacuolation, 12 (24%) cases central necrosis, 4 (8%) cases focal necrosis, 26 (52%) cases central congestion, 10 (20%) cases diffuse congestion, 5 (10%) cases increase in periportal tissue, 4 (8%) cases lymphoid infiltration of periportal tissue, 1 (2%) case multiple abscesses, 1 (2%) case conglomerate tubercles. Kidney: 8 (16%) cases negative, 42 (84%) cases show lesions, 10 (20%) cases chronic interstitial nephritis, 17 (34%) cases chronic diffuse nephritis, 31 (62%) cases arteriosclerosis, 13 (26%) cases acute parencyhmatous nephritis, 1 (2%) case multiple abscesses, 1 (2%) case tuberculosis.

SUTURE OF THE FAUCIAL PILLARS FOR HEMORRHAGE FOLLOWING TONSILLECTOMY.

R. H. GILPATRICK, M.D., BOSTON.

THE possibility of serious bleeding and even of fatalities from this cause, following removal of tonsils, must always be borne in mind even where there is no previous history of hemorrhagic tendencies. Three cases of this sort which have come under my observation have convinced me that firm and complete approximation of the faucial pillars by suture is the most efficient means of controlling the bleeding. In the first two cases the technical difficulties of this procedure were so great that I was led to adopt a method of securing the suture without knots.

The difficulty of the operation is due to the small space in which the work must be done, failure to obtain a view of the lowest portion of the pillars, where the suture must begin if it is to be efficient, and tying of knots. Suture of the pillars

is so radical a procedure as to be advisable only in cases of continuance of bleeding after the application of the usual means of control. In such cases I have found it a life-saving measure. The method of securing the suture with perforated shot was tried in my last case and proved itself so efficient and easy that it seemed worth while to describe it. Not having had opportunity to look through the literature I make no claim of originality, but never having heard of its previous use in such circumstances I offer it for what it may be worth.

The operation usually has to be done without anesthesia, and the condition of the patient is often such that none is needed. The choice of position in which the patient is best put rests on the individual operator and the circumstances. I have used the Rose position with satisfaction. Good light is of course necessary. In the Rose position the patient's head is but little elevated above the chest, which point is worth considering

in a nearly exsanguinated patient. At the same time, less blood and mucus are likely to be inhaled. The jaws must be opened to their full extent, and the tongue kept on the floor of the mouth. This is best done with the Whitehead self-retaining gag with attached tongue-depressor. A small, round-pointed, fishhook-shaped needle is threaded with black linen or silk. The thread should be about eighteen inches in length. A long-shanked Mayo needle holder has proved adaptable. When the suture is ready to be placed, the pharynx is quickly wiped out and an ordinary right-angled metal tongue-depressor introduced so that its tip presses against the base of the tongue just at the lowest point of the faucial pillars and away from the side being operated upon. This gives a view of the point at which the first bite of the needle should be made. The point of the needle is carried behind the lowest portion of the posterior pillar and is introduced forward through both pillars, taking enough tissue to insure its not tearing out. This step in the operation is shown in Fig. I. The needle is pulled through, leaving the tail of the suture sufficiently long to reach beyond the incisors where it is twisted with the main portion of the suture between the thumb and forefinger. A perforated shot is now slipped over the needle and tail of the suture and the shot grasped in the jaws of the needle holder. One hand holds the twisted suture taut while the other, grasping the needle holder, forces the shot against the point of suture of the pillars and crushes it upon the thread. The tail of the suture is now forced between two convenient teeth and the suture continued as a running, over and over, to the other end of the pillars. The bites should be about a quarter of an inch apart and should include sufficient tissue to prevent tearing out.

The last step in the operation is shown in Fig. 2. The tail of the suture has been left long, the suture drawn tight, and the head and tail of the suture twisted together as before. Another perforated shot is slipped over the needle, grasped in the holder, forced against the point of suture of the pillars and crushed. If the ends of the suture are left permanently long and secured to teeth, it will do away with the possibility of the shot dropping into the larynx in case the suture should break or tear out.

The advantages of this method, as I have found them, are, ease of application, short time required and security with which the pillars are approximated and bleeding controlled. As soon as the suture is passed through the pillars the second tongue-depressor may be removed out of the way, for the placing of the shot does not require that the tongue be held away. The suture furnishes a guide along which the shot is pushed until it reaches the pillars.

Reports of Societies.

THE AMERICAN NEUROLOGICAL ASSOCIATION.

THIRTY-SIXTH ANNUAL MEETING,
MAY 2, 3 AND 4, 1910.

TUESDAY MORNING SESSION.

(Continued from No. 2, p. 64.)

A CASE OF FRACTURE OF THE BODIES OF THE FOURTH, FIFTH AND SIXTH CERVICAL VERTEBRÆ WITH INJURY OF THE SPINAL CORD.

DR. W. H. SWAN, of Colorado Springs; DR. CHARLES A. POWERS, DR. HOWELL T. PERSHING, Denver: A man, aged seventy, fell from a stumbling horse, striking on his forehead. There was immediate motor and sensory paralysis below the neck, with evacuation of bladder and bowel, without loss of consciousness. Extreme shock, followed for some months by improvement, without restoration of ability to stand, sit alone or turn in bed. Daily catheterization was done with no ill effects. Eczema, which was present, rapidly disappeared on the anesthetic skin up to a sharp line of demarcation, then slowly cleared above. There was greater mental activity and happier mental state during about eighteen months than before injury, probably

due to relief from unpleasant sensations. Death took place twenty-eight and one-half months after injury, from uremia. Operation was considered and rejected on account of patient's age and the improbability that a remediable lesion would be found. Fixation of head was deemed unadvisable. The dried preparation of the cervical spine of this patient shows no lesion of the arches or articular processes, but a moderate crushing of three bodies, which could not have been remedied by operation. Localization diagnosis was based on retention of power in deltoids and biceps, with paralysis of both triceps muscles which indicated a lesion of the seventh cervical segment. Faradic tests indicated almost complete escape of anterior gray horns and anterior roots. Autopsy showed the bodies of the fourth, fifth and, to a lesser extent, the sixth cervical vertebræ to have been fractured by a crushing force, but the fragments united in normal position. The arches and articular processes showed no injury. Preliminary histological examination shows the usual ascending and descending degeneration.

DISCUSSION.

Dr. Harold N. Moyer, of Chicago: This case follows the general rule that the fifth cervical is the most frequent seat of these cervical fractures. So far as operation is concerned, this case rather favors operation. The value of operation in these cases is unquestioned. The distinguishing features for the neurologist is to understand if there is extrinsic pressure. The hematomyelia is not, of course, to be operated upon. I do not wish to be understood as saying that this old man of seventy ought to have been operated on. I am speaking of the broad general principle of operation. I believe it to be a sound rule to fix the cervical vertebræ where you have a fracture if you don't operate. At least in all the cases I have seen I have recommended fixation.

Dr. Pershing, closing: When it comes to a question of operation in a case of this kind, you have to consider the individual patient, but you have also to consider the advantage of accomplishing anything when you do your operation. In this case, of course, we could not have reached the seat of fracture in the bodies and done anything with them. The risk from the operation *per se* is very great and, of course, with this particular man, would have been very much greater. There were many things aside from his age which made it necessary to be very cautious about operation. The question of fixation was discussed very carefully and very earnestly and it was decided in the negative, mainly on account of the absence of rigidity and pain; the disposition of the patient after being warned was to keep his head still on the pillow. Also because of his temperament it would have been very difficult to have made him submit to fixation.

DISTURBANCE OF SENSATION IN A CASE OF SYRINGOMYELIA.

Dr. Hugh T. Patrick, of Chicago: I would like to show a case in which the hypophysis has been removed. The patient illustrates the occasional usefulness of the neurologist and the esteem in which he is held in some quarters. Last June I made the diagnosis of tumor of the hypophysis in the man which I present. Dr. A. E. Halsted, of Chicago, was called on to operate and he had the nerve to operate and removed the hypophysis successfully. The man made a beautiful recovery and his vision, which had almost disappeared, has returned in a very large measure. He had been able to see only very faintly, that is, the face of an individual looked like a blurred white something, and now he is able to read a newspaper. I am sorry I cannot give the details of the clever surgical work in this case.

Dr. David D. Wolfstein, Cincinnati: What were he symptoms in this case?

Dr. Patrick: The man had blurred disks, not choked disks, and had the typical hemianopsia. The x-rays showed an enlarged sella turcica; some slight mental hebetude, but not a great deal.

Dr. A. E. Halsted, of Chicago: In operating on the patient I followed the usual preparation. The anesthetic was started with ether. A high tracheotomy was done and a Trendelenburg balloon canula inserted. Chloroform was now used for the anesthetic. The nasal cavities were packed with adrenalin gauze and the pharynx tamponed. The upper lip was raised and an incision made in its mucous membrane about five sixths of an inch from the muco-cutaneous junction, and parallel to the alveolar process. The soft tissues were freed and the nose gradually drawn up with retractors. The septum was divided with bone forceps and displaced upwards and laterally. The lower turbinates, the vomer and the perpendicular plate of the ethmoid were removed. At a previous operation, at the Illinois Charitable Eye and Ear Infirmary, the middle turbinates had been removed by Dr. Norval H. Pierce. An opening was then made through the anterior wall of the sphenoidal sinus and a blue-colored pulsating mass seen. The membrane covering the tumor protruding into the opening into the sphenoid was incised. The tumor was then curetted out with a dull curette. The whole cavity, now the shape of a cylinder, 1 inch in diameter and 5 inches long, was thoroughly flushed with normal salt solution and subsequently packed with iodoform gauze. The septum was sutured back, and the mucous membrane of the mouth replaced and sutured, and the tracheotomy tube removed. During the first forty-eight hours the patient's temperature varied from 100 to 102 rectally, and the pulse from 100 to 120. His condition was fair, his mind clear and he was free from pain. At the end of forty-eight hours the packing was removed and replaced immediately by the senior house surgeon. Following the repacking of the cavity the temperature rapidly rose until it reached 105, with a pulse of 160. The patient became somnolent and could only be aroused with difficulty. This condition lasted for twenty-four hours. Upon removing the gauze pack and irrigating the cavity, the temperature fell rapidly until, at the beginning of the fourth day, his temperature reached normal, and from that time on no untoward symptoms developed. The patient left the hospital at the end of five weeks, free from pain, and with marked improvement in the vision. The right eye was 4-200 before operation, and at the end of the second week after operation it was 6-15; left eye was 5-200 before operation and 6-22 after the operation. He continued to improve, resuming his occupation as driver of an express wagon on the first of December, and since that time has enjoyed good health.

Dr. James J. Putnam, Boston: In the case of a young man, with a temporal hemianopsia and an almost complete loss of sight, the x-rays showed a large sella turcica. A diagnosis of tumor of the hypophysis was made. Operation was done and a cyst containing 1 1-2 oz. of fluid was found and the patient made a complete recovery. The eyesight has been restored almost to normal, although considerable atrophy of the optic nerve has taken place.

MYOSITIS FIBROSA FOLLOWING NERVOUS BREAKDOWN.

Dr. John K. Mitchell, of Philadelphia: A nervous breakdown from overwork was followed by an attack

of fever of unknown origin, with great prostration. Four months later a stiffness in the extensors of one thigh was noticed. A like stiffness and hardness successively appeared in muscles of other parts. This increased in degree until the patient was almost crippled. A portion of muscle excised during life exhibited widespread fibrous degeneration, the muscle fibers being in some places replaced by fibrous tissue, in others pushed aside by it. In cross-section radiating striæ, apparently of fibrous tissue, are seen. The patient improved under treatment.

WEDNESDAY MORNING SESSION.

DR. M. PRINCE, the President, called the meeting to order at 10 A. M.

FRIEDREICH'S ATAXIA.

DR. WILLIAM G. SPILLER, of Philadelphia: The symptoms of this disease have been known many years, but the pathology has been very imperfectly studied. In the case which I report, in addition to the usual findings in the spinal cord, the peripheral nerves were greatly degenerated; recent degeneration detectable by the Marchi method was seen in some of the muscle fibers, and the cerebellar nuclei showed alteration of the nerve cells. Many naked axis cylinders were detected by the Bielschowsky stain in the columns of Goll, which by the Weigert hematoxylin stain appeared almost completely degenerated. Friedreich's ataxia is not a degeneration confined to the spinal cord of cerebellum, but is the result of implication of the entire central and peripheral nervous systems.

DR. SIDNEY I. SCHWAB, St. Louis: What was the mental status of this case? Was there any suggestion of any syphilitic etiology?

DR. E. W. TAYLOR, Boston: In one case which I studied there was a strikingly beautiful degeneration of the cerebellar tract and of Gower's tract, which I took to be part of the widespread degeneration throughout the nervous system. I would ask whether Dr. Spiller was able to trace this degeneration of Gower's tract into the cerebellum, and whether anything has been done towards tracing Gower's tract and the cerebellar tract towards their terminations.

DR. B. SACHS, New York: The attempt to explain hereditary family diseases in connection with the modern laws of heredity will have to be made some day and, even though our first steps may be very infantile, we should make a beginning. The distinction between Friedreich's ataxia and amaurotic family idiocy is interesting. That is one point that might be taken up for the starting point of consideration of family diseases. In hereditary ataxia we evidently have an involvement chiefly of tracts of peripheral structures, as Dr. Spiller has so well shown, and no doubt there is some cellular involvement as well, while amaurotic family idiocy is a purely cellular disease. Some years ago these cases were spoken of as cases of arrested development. The biologists and sociologists are not satisfied with that, particularly if the symptoms come on later in life after normal birth, and so on. These family diseases would not occur if there were not some vital defect in the germ plasm. That vital defect makes the organism less resistant to extraneous influences or to influences within the body than it would be if this vital defect in the germ plasm did not exist. In former days I was absolutely opposed to the idea that any family disease could be due to any toxic or infectious agent. I do not believe that any family disease can be due to an extraneous toxic or infectious agent, but an infectious agent that is formed within the body itself is conceivable, particularly if you allow that the injury done to the germ plasm in the first place makes the various structures of the body less resistant to poisons formed within the body itself. That is the one step forward that we are able to take in the matter of explaining some of the family diseases. What its application will be to Friedreich's ataxia I do not know, but would like to insist that we go one step further than such careful anatomical, histological work as that reported this morning and endeavor to bring the various family diseases in line about so much which is being written, in which all of us are so much interested.

DR. SPILLER, closing: The Wassermann reaction was not taken, but there were no clinical manifestations of syphilis. The pathology shows no round-cell infiltration such as is characteristic of the nervous system. In reply to Dr. Taylor's question, Gower's tract was not degenerated, although in many cases of Friedreich's ataxia it has been. Cellular changes are not usually found in Friedreich's ataxia, according to report. The nucleus dentatus in this case showed decided cellular changes. There were also some changes in the cortex.

PERSONAL EXPERIENCE WITH FREUD'S ANALYTIC METHOD.

DR. JAMES J. PUTNAM, Boston: The purpose of this paper is twofold: First, to indicate the character of the author's own successes and failures in the application of Freud's method of psycho-analysis; next, to indicate the respects in which that method seems to me of importance and the points of view from which it should be studied.

In so far as Freud has shown us a valuable means of studying the processes which go on unconsciously within our minds, and the respects in which they lead to traits of character and temperament, it is difficult to see how any one can fail to recognize the importance of his work. Most of the criticisms have come from persons who have failed to verify his conclusions. That, however, is a different matter, although in the author's opinion, based upon his own observations, the more carefully and thoroughly the method is applied, the more accurately the conclusions derived from it will be found to coincide with those laid down by Freud and others who have followed in his footsteps. The only personal observations which the reader would present as conclusive are those made on about six cases studied during the past year. A brief summary is given of certain of these cases with a view of indicating the difficulties which attend the application of the method, whether to the dream life or to the waking life, as well as the character and degree of success obtained in treatment. Incidentally, comparison is made between this and other methods with reference to their relative value. It is obvious that the talents and interests of neurologists are not all of the same sort, and for those to whom the study of the mind in health and in disease appears the most important portion of the physician's work, the contributions of this relatively new field are certain to seem of marvelous promise and of immense practical importance.

DISCUSSION.

DR. GEORGE L. WALTON, Boston: I wish that Dante could open this discussion and let us know whether, when he credited Desire with being the root of all things good and evil, he had in mind unconscious memory pictures, as of dreams, to which branch of the subject I will confine myself in this discussion. Without venturing to offer a complete explanation of the dream, I feel justified in assuming that it consists of a series of concepts previously entertained but newly assembled, succeeding each other, sometimes with lightning-like rapidity. One important difference

between these memory pictures and those of the waking life is the inability of the dreamer to measure time and space; but the main distinction lies, perhaps, in the absence of goal ideas and of the power of control which enable us in our waking hours to guide our thoughts more or less successfully in definite channels.

The associations by which these pictures are assembled will vary with the individual and be tinged by his emotional tone, but to read into them, however ingeniously, the fulfillment of desires is to strain a point and to substitute a preconceived notion for the study of facts. I find it hard seriously to discuss Freud's illustrative case of a child of tender years who sleeps in a very large bed and dreams he is in a tight place. This dream Freud explains as the fulfillment of the child's wish to be large, a wish so abundantly fulfilled that he thinks himself so large that even this bed is too small for him. To credit mere memory pictures, distorted at that, with being symbols is unduly to glorify the dream state—I should perhaps rather say unduly to debase it when the symbols are of the character which permeates the works of this author. At the risk of seeming prejudiced, I find myself disinclined further to follow the leader whose book on dreams contains that of a young woman who thinks she holds in her hand a branch of a tree, which is assumed to symbolize subjects from which her thoughts should rather be diverted, and in which it appears that breaking off such a limb presents an equally objectionable suggestion. The reproduction of a dream in detail, and its analysis, is not only baffling and valueless, in my opinion, for medical practice, but may be harmful. Sholtze says that children should not be encouraged to relate their dreams, for their already fantastic imaginations will thereby be the more led away from the real things of life. Similarly, in the treatment of the psychoneurotic, the desideratum is concentration upon the external and the real. As to the comparison between getting up and doing something and analyzing the dream, it seems to me that an ounce of Muldoon is worth a pound of Freud.

Dr. Edward B. Angell, Rochester: I agree with Dr. Walton. These patients need ruthless treatment. I recall a patient sent to me whom I required to sit up and every time the doubts came upon her to say out loud, "What a damn fool I am!" Two treatments of that sort served to relieve the whole chain.

Dr. B. Sachs, New York: I desire to be absolutely impartial in this matter, not only out of respect for the reader of the paper, but because personally I have been acquainted with Freud for twenty-five years, ever since we sat in Meynert's clinic. I would agree with anything of Freud's with special delight if I could feel that his teachings are absolutely sound. There are several practical reasons why they do not appeal to me: The first counts least, that is, the length of time the examination takes, and the smallness of the result. For instance, it took six weeks for my assistant to get the history of masturbation, which I must confess I knew existed when I looked at the boy. That is an enormous waste of time. The most serious objection to the method is that it has had a distinct sexual taint given it. Whether all the channels lead up to that special function or not I do not know, but the sexual taint is most marked. It may be of great interest to the neurologist to find out that some sexual misconception or some disagreeable sexual thought had existed in that person in early years, but, while it may be of great interest to the physician, and while it may not do a woman of forty any harm to have her psychic analysis made as carefully as Dr. Putnam has performed it, it is my firm conviction that we do no good by taking a young woman of fourteen to twenty and pushing her thought back on that one sexual mistake, not a conscious sexual mistake, that was made early in life. I cannot see that the therapeutic results have been any better, nor have they been arrived at any quicker than by the older methods.

Dr. Charles L. Dana, of New York: I would welcome any new method that would help us in studying this serious class of cases, especially a method that Dr. Putnam had taken so seriously and found some real good in. My practical experience has been not only of failure, but often of disaster with Freud's method. Taking the case of a well-educated and delicate-minded man or woman and making them go through the details of early experiences has sometimes just stirred up a mass of old memories has thrown them into almost delirium at times. It has often at times been most unfortunate and I have practically stopped giving any such treatment in cases of at least the more educated, more intelligent type of patient that comes to me. In dispensary practice perhaps we can find rather more scope for the method. In the minor cases of this class of psychoneuroses I find that by ordinary methods, treatment, education and modern resources of therapeutics they get well. I always tell psychasthenic cases that they will get well, and they generally do. It must be remembered that a certain number of cases run a course — they get well whether you do anything or not in one or two years. There is another group of cases, more serious, which date back to early life; these are serious cases I have not been able to do much with. If this method will successfully help them, it will be of value, but I do not see exactly how the philosophy of the method could explain or help a condition which is essentially constitutional. Instead of the Freud method, the quickest way of getting at the inside of these cases is to do what we practically all try to do and often succeed. I take cases of this kind, put them in a private hospital and give them an intelligent nurse; I go to see them often, and send masseurs whom I know to be intelligent women or men to give them treatment and by every process that I know of I become acquainted with their story. In two or three weeks one learns about these patients; he knows their past history, and I do not believe you can get as much by the Freud method as by our present method. I think we have much better methods than that of Freud.

Dr. L. F. Barker, of Baltimore: It has been my good or bad fortune to see a good many of these patients in the last few years. Any method which helps us to understand the nature of these cases and treat them successfully should be welcome. I am very glad indeed that so fine a man as Dr. Putnam should undertake this study,—the practical testing of Freud's method. It seems to me that the method should be tested by a man in whom we have absolute confidence, whose ethical nature is such that we could have no doubt of the motives of the study. I think the method should be carefully tested. It has excited world-wide interest, and some of the better psychologists have become very enthusiastic about it. It is too early to say how much good will come of it, but certainly a large amount of new knowledge concerning the psychology of these patients, the psychology of life generally, is being derived from these studies. I think we should separate the method of psycho-analysis from the purely sexual idea. In my application of psycho-analysis it has been very helpful, especially in extending the anamnesis. As to psychasthenic cases, my experience with them is that they are hereditarily badly endowed people. They start badly.

Most of them come from generations of neurotic people. I have in mind some cases under my care where for three generations this condition existed. This may come at any time of life, though most of them have attacks early in life.

DR. CHARLES K. MILLS, of Philadelphia: What has been said by Dr. Dana and Dr. Barker so well expresses my own views in regard to the matter that there is little left to be said. We owe a debt to Dr. Putnam for the manner in which he has approached and attempted to develop this subject. However, I am not in accord with Dr. Putnam's views. The reports so far have not been altogether satisfactory. The cures do not seem to be in greater number or better than those obtained by the old methods.

DR. HUGH T. PATRICK, of Chicago: Dr. Putnam's method does not differ so very much from the ordinary methods of psycho-analysis. It seems to me that psycho-analysis, or whatever leads us to get back to the definite original cause of any phenomenon in the abnormal patient, or the beginning of what has been the series of abnormal phenomena, is a help. What I believe to be distinctly injurious is to encourage the patient to probe himself when he is by himself, without control and without the leading intelligence of his physician, into his past life, because we all know that patients are unable to observe facts without conclusions, to observe phenomena without interpretation, and it is particularly these neurotic, poorly balanced, hypersensitive people who are constantly drawing wrong conclusions. This is distinctly dangerous, and it is that particular part of the Freud method with which I am at variance.

DR. A. R. ALLEN, Philadelphia: Dr. Dana has said that most of these cases will get well if let alone. No doubt one sees cases that have been the rounds, having been treated by neurologists in a routine way, and well treated, too, and he tries himself to treat them and fails utterly until he uses the Freud probe.

DR. AUGUSTUS A. ESHNER, of Philadelphia: It should be borne in mind that these patients are already unduly subjective and introspective, and that care should be taken not to make them more so as a result of a certain form of interrogation. Herein appears to reside a danger entitled to serious consideration.

DR. HAROLD N. MOYER, Chicago: I am a disciple of Putnam rather than of Freud. Any one who undertakes to practice Freud's analysis upon his patients on their first visit to the office will soon have no patients. That is obvious. The older methods are to be adhered to for a certain time. As to the psycho-analysis of impotence, the physician who neglects to look for some prostatic trouble or stricture will probably fail. This discussion brought out so far that the old methods are efficient, as a rule, but there is a certain residuum of cases not relieved by ordinary methods and for whom is left this psycho-analysis; it is a distinct, adequate, efficient method of getting at a few cases that we had not succeeded with before until it was offered to us.

DR. PHILIP COOMBS KNAPP, Boston: On the first appearance of Freud's work I began to try Freud's method. There is one radical defect in Freud's general position which has not been touched upon. We see almost every day cases of nervous disturbance of one sort or another due clearly and confessedly to some pronounced emotional disturbance. The cases improve as the emotional disturbance is put into the background and forgotten. It does not seem always to be a reasonable method of treatment in those cases which are due to a forgotten emotional disturbance to drag that once more into the field and get the patient to dwell upon it. It seems to me this is the primary unreasonableness of the views of Freud. There is a tendency to consider the date derived from the psycho-analytic methods as being absolutely accurate, but I have not always found them so.

(To be continued.)

Book Reviews.

Prescription Writing and Formulary. By JOHN M. SWAN, M.D., Associate Professor of Clinical Medicine in the Medico-Chirurgical College of Philadelphia, etc. W. B. Saunders Company. 1910.

This small volume of 185 pages contains 1,043 prescriptions, preceded by information and facts regarding the construction of prescriptions and the method of writing them, with chapters also on the United States Pharmacopeia, weights and measures, doses and incompatibility. A compendium of this sort, while useful, is nevertheless of limited value as a guide to treatment. Treatment of diseases like poliomyelitis, for example, by indifferent drugs can in no way represent the progress of medical practice. The same is naturally true of many other conditions.

The Elements of the Science of Nutrition. By GRAHAM LUSK, Ph.D., Sc.D., F.R.S. (Edin.). Second edition, revised and enlarged. Philadelphia and London: W. B. Saunders Company. 1909.

Nutrition and Dietetics. A Manual for Students of Medicine, for Trained Nurses and for Dietitians in Hospitals and Other Institutions. By WINFIELD S. HALL, Ph.D., M.D. New York and London: D. Appleton & Co. 1910.

These two volumes are complementary. The former, a second edition of Lusk's well-known work, aims to review, in fairly technical and scientific manner, the experimental data on which rests our knowledge of nutrition in health and in disease. The latter, a new publication, undertakes to present in more practical, didactic form, for medical students, nurses and general practitioners, the details and methods of application of this knowledge to the actual, specific problems of dietetics. Each is admirable in its particular field. Lusk's new edition brings up to date a textbook of standard value and convenient reference, especially for investigators in the physiology and pathology of metabolism. Hall's book, presenting as it does the result of the author's experience in teaching nutrition and dietetics, should meet the definite need of a less technical manual on these subjects. Both volumes are well arranged and adequately illustrated.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JULY 21, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 Tremont Street, Boston, Mass.

THE PREVENTION OF OPHTHALMIA NEONATORUM.

The prevention of *ophthalmia neonatorum* has for years been a commonplace of medical knowledge. Since 1905, this disease has been reportable to our local boards of health, and it has been the duty of these boards to take immediate measures for every reported case in order that blindness might not ensue. Yet among 5,949 babies, or almost half the births recorded in five Massachusetts cities in 1909, 42% were attended by physicians who never use a prophylactic for ophthalmia neonatorum. Though these physicians have far larger practises than their more cautious confrères, their cases of ophthalmia neonatorum are disproportionately many, and the results are serious. Their omission of a well-known and harmless preventive is responsible for disease among many of their patients, and for blindness among a few.

The situation is serious. Child after child is still going blind from ophthalmia neonatorum; a nursery and a kindergarten must be maintained for their care, a school provided for their special education, and the people taxed for their industrial assistance through years of darkness; all this for no necessary cause. The responsibility, moreover, does not rest alone on those more careless physicians who never employ a preventive. Among the 5,949 babies already mentioned, only 17% were attended at birth by that honorable minority carrying out preventive treatment in every case. The remaining 41% were attended by physicians who use a prophylactic only as their judgment dictates. Unfortunately, their judgment is fallible, and the children pay the penalty.

It is true, of course, that physicians in excellent standing differ as to the advisability of routine prophylactic treatment for this disease. But where such men differ, should not the safer practise prevail? One case suggests the answer. The father, supposing that he had not infected his wife, assured the attending physician that there was no possibility of danger to the eyes of the baby about to be born. The young man had the best of reputations. The physician accepted his assurance; omitted the 1% nitrate of silver solution which he otherwise would have used, and soon found himself with so virulent a case of ophthalmia neonatorum on his hands that even good hospital treatment failed to save the eyes. As the physician in question remarked, "That one case proved to me that I should use the solution in every case, with the possible exception of my own family." It is useless to say that the father was responsible. He was. But what of it? For the child's sake, and for the state's, it was the physician's duty to forestall the chance of blindness.

Such, at any rate, is coming to be the view of the authorities most familiar with the facts. In a moderately worded but significant official letter to all registered physicians in the commonwealth, Dr. M. W. Richardson, Secretary of the State Board of Health, says, "The possibility of any baby becoming infected at the time of confinement should be constantly borne in mind, and *it is desirable to carry out a routine preventive treatment in every case.*" The italics are Dr. Richardson's. The board, moreover, is no less emphatic in deeds than in these words. In conformity with a law passed at the last session of the legislature, it is preparing to distribute to all registered physicians a 1% solution of nitrate of silver in a special Stearns dropper of protective colored glass. This convenient container, which is practically a small bottle with a rubber bottom and a dropper-shaped neck, holds enough of the solution for use at a number of births; and an extra supply can be got at all local antitoxin stations. Every physician practising obstetrics should, therefore, keep one of the droppers in his bag, for use at every confinement. The solution, of standard strength and contained in glass of a protective color, can be relied on even after considerable lapses of time. This alone will be a relief to many physicians. The fact, too, that it is supplied by the state, and its use officially recommended, should silence the objections sometimes successfully urged by frightened and ignorant parents. For the future, such objections

should not avail with reputable physicians, and it is to be hoped that they will not only use these droppers at every confinement which they attend, but supply them also to nurses and others, so that all persons attending confinements may be reminded of the need for preventive treatment.

Prevention, however, is unfortunately not the one thing needful. If the present constant sequence of neglected cases, baby after baby needlessly blind, is no longer to disgrace this state, ophthalmia neonatorum must be reported according to law. Until it was made reportable to the State Board of Health, most physicians did not know that this disease should be reported to the local boards. Outside of Boston, therefore, the law was a dead letter until the State Board, about a year ago, called it to the attention of physicians throughout the commonwealth. Even since then, the law has received scant respect. The reason is not far to seek. Physicians unfamiliar with the wording of the law have supposed that only gonorrheal ophthalmia should be reported. And so, where the diagnosis was uncertain, they have either failed to report, or have delayed till they secured a positive bacteriological test. Or again, though reasonably sure of their diagnosis, they have failed to report, for fear of marking their patients with the stigma of gonorrhea. For these reasons, and from gross carelessness, physicians have reported but few of their cases. In seven Massachusetts cities, for example, an incomplete canvass shows more than three times as many cases in 1909 as were reported.

Such laxity would hamper the most active board of health and has doubtless discouraged others in the discharge of their duty to secure adequate treatment for those secondary cases which may occur despite the physician's best efforts, as well as for cases following neglect of preventive measures. The pitiful results, in eyes disfigured and in lives cut off from the light, are already too disgracefully familiar. Words on this subject are wasted that do not show the way to removing our disgrace. The way is sufficiently plain. Let physicians, first, themselves obey the law; then let them see to it that boards of health do likewise. Let physicians report, as the law requires, every case where an infant's eyes "become swollen and red, and show an unnatural discharge." Then let them insist that, in their own practise, as in others, the board of health shall follow each case up, demanding and enforcing adequate treatment. By reporting every case, regardless of diagnosis, physicians will destroy the superstition which associates ophthalmia neonatorum exclusively with gonorrhea; they will thus remove the gonorrheal stigma from reporting; they will make reporting prompt as well as complete; and, for the first time, make it possible for boards of health to take quick and efficient action. Only by these means can the physicians, who are responsible, remove this commonwealth's disgrace — its toleration of our blinding of the innocents.

ADVISABILITY OF ANTITYPHOID INOCULATION.

THE annual recurrence of the vacation season will doubtless be marked by the usual increased incidence of typhoid fever in the United States, especially among those people who leave the relative security of the cities and expose themselves, at home and abroad, to repeated opportunities of infection from various and unguarded sources of water-supply. The question arises whether the likelihood of such infection might not be miminized by more extensive use of antityphoid inoculation.

At the time of the Boer War in South Africa, initial experiments were made in the British Army with injections of sterilized cultures of typhoid bacilli in the hope of producing an artificial immunity to the disease; and, in point of fact, the soldiers in regiments thus treated showed a considerably lower percentage of typhoid incidence than did other and uninoculated troops under similar conditions in the field. Since that time the development of Wright's opsonic theory and improvement of the technic of bacteriotherapy have done much to explain the nature of the process involved and to facilitate its intelligent application. The series of publications by Leishman and Harrison in the *Journal of the Royal Army Medical Corps* in 1907 sum up the work of the British Commission on this subject to the present date.

The idea of preventive inoculation against typhoid was late in introduction into America. In August, 1909, in a communication to the *American Journal of Public Hygiene*, Dr. L. H. Spooner, of Boston, called attention to the relatively high incidence of typhoid among nurses and others particularly exposed to infection from handling patients with the disease, even under the observation of due precautions and with the best facilities for disposing of infectious material. In the issue of this JOURNAL for Jan. 13, 1910 (Vol. CLXII, p. 37), Dr. Spooner further published

the results of several series of antityphoid inoculations of nurses, house-officers and ward-tenders which he had conducted at the Massachusetts General Hospital and at the Chelsea Naval Hospital. This piece of research, originally suggested by Dr. Mark W. Richardson, secretary of the Massachusetts State Board of Health, went far towards demonstrating that such inoculation does establish a considerable degree of immunity; for not only did all those inoculated develop a fairly active and persistent Widal reaction, but in the six months which elapsed between the beginning of the experiment and the publication of the article, not one of them contracted typhoid fever, though all continued to be exceptionally exposed as before. A similar series of experimental inoculations has also been conducted during the past year by medical officers in the United States Army.

Of course the proof of any theory is its successful application. The duration and degree of protection afforded by this procedure, and the possibility of its perfection so as to give complete security, remain to be determined. Meantime, it seems to offer a sufficient amount of immunity, attainable with relatively little and transitory discomfort, and with absolute safety, to be worth while for any one liable to special exposure. It may be found that repeated inoculations will maintain or establish permanent immunity. At any rate, it seems wise and advisable for all whose regular work or whose recreation during the summer season may expose them to unusual risk of typhoid infection to avail themselves of this means of protection, even if only partial, against a disease which, in its possible complications and sequelæ, is one of the most to be dreaded in the whole category of bacterial infections.

THE CITY AND ITS CONSUMPTIVES.

Two aspects of tuberculosis have recently been engaging the public's attention. One is the prevention of recrudescence; the other is the detection of early cases, and their relation to public charities.

It is often said, and with truth, that many persons in whom the progress of the disease has been arrested return to their former unhygienic life only to suffer from a renewed activity of their tuberculosis.

For people of ample means, who can command air, light and food, the remedy for this is easy. But for the far greater number, those of limited means, who have to earn their living in the city, there has been in the past little encouragement. For such, the Home in Mattapan, near Boston, should be a godsend. There one may have an airy bedroom, good bathing facilities and proper food at a cost of six dollars a week.

For the detection of early cases, the chairman of the board of trustees of the Boston Consumptives' Hospital Department suggests that the city set a good example by having all its employees undergo physical examination. In the open letter in which he makes this suggestion, he describes the Elberfeld system for handling consumptives. This system, named after the Prussian city in which it originated, provides for the division of the city into sections, each of about three hundred persons. Fourteen such sections comprise one district. Over each section is an almoner, who gives to applicants not only financial aid, but practical assistance by the loaning of tools and by finding employment; over each district is an overseer, and over all is a central committee of four councillors, four citizens and the mayor.

Such an institution might do for the city at large what the Social Service is doing for the patients of certain hospitals. After the need for purely medical assistance is past, the patients are watched, aided and encouraged to regain complete health, instead of dragging along for months in a semi-invalid condition.

MEDICAL NOTES.

An Unusual Medical Situation. — At a Portland, Ore., hospital, two women according to the report have recently been operated upon by their sister, while a fourth sister acted as nurse.

A Model City. — At Corey, Ala., the United States Steel Corporation is building a city for the workers in its new plant. All the problems of modern municipal development have been considered — sanitation, transportation and ornamentation.

Infant Mortality in Cleveland. — Statistics recently published show that for the past three years (1907–09) the infant mortality in Cleveland, Ohio, has been approximately 25% of the total deaths in that city. During the same period, about two thirds of the infant deaths were due to diseases of the digestive system. These figures indicate nothing "new

or never told before," but serve to reiterate and emphasize the truth that alimentation is the most serious problem of infancy, and that the improvement of methods of infant feeding is the surest and most important agent in the reduction of infant mortality.

ILLEGITIMATE USE OF OPIUM AND COCAINE IN THE UNITED STATES. — According to the reported statements made by Dr. Hamilton Wright, United States member of the International Opium Conference, before the recent annual convention of the Pennsylvania State Pharmaceutical Association, 400,000 pounds of opium and 150,000 ounces of cocaine were imported last year into this country, and 75% of the opium and 90% of the cocaine were used by drug habitués. It is estimated that 168,000 pounds of opium were used for smoking — 68,000 by native Americans, 100,000 by the Chinese, of whom there are 150,000 in the United States. Nearly 50% of all criminals and over 21% of prostitutes are said to be addicted to some drug habit. These figures, if correct, need no comment. Dr. Wright further estimates that 2¼% of all physicians and 1.32% of all nurses in this country have the morphine or cocaine habit.

INTERNATIONAL CONGRESS OF OBSTETRICS AND GYNECOLOGY. — The fifth International Congress of Obstetrics and Gynecology, which occurs at St. Petersburg, Russia, in September, will be held at the Imperial Institute of Midwifery and Gynecology, No. 3 University Line, Vasilievsky Ostroff. A feature of the occasion is an exhibition which is to be held in connection with the congress and to which the Committee of Organization is inviting exhibits from all parts of the world. Following are some of the things which will be displayed at this exhibition: Surgical instruments, modern and ancient; objects pertaining to the equipment of laboratories, operating and lying-in rooms, etc.; objects relating to the nursing of newborn infants; plans of obstetrical clinics and gynecological sections of hospitals; objects for the study of midwifery and gynecology; portraits of medical men who have distinguished themselves in the history of midwifery and gynecology; books on gynecology and midwifery; pharmaceutical preparations, etc. Exhibits should be delivered at their destination not later than Sept. 1, addressed as follows: "For the Exhibition in Connection with the Fifth International Congress of Obstetrics and Gynecology, No. 3 University Line, Vasilievsky Ostroff, St. Petersburg."

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, July 13, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 32, scarlatina 17, typhoid fever 7, measles 84, smallpox 0, tuberculosis 93.

The death-rate of the reported deaths for the week ending July 13, 1910, was 20.20.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, noon, July 16, 1910, was 221, against 163 the corresponding week of last year, showing an increase of 58 deaths and making the death-rate for the week 18.30. Of this number 115 were males and 106 were females; 217 were white and 4 colored; 143 were born in the United States, 75 in foreign countries and 3 unknown; 51 were of American parentage, 144 of foreign parentage and 26 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 38 cases and 3 deaths; scarlatina, 20 cases and 0 deaths; typhoid fever, 11 cases and 1 death; measles, 55 cases and 2 deaths; tuberculosis, 105 cases and 21 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 17, whooping cough 1, heart disease 24, bronchitis 1. There were 12 deaths from violent causes. The number of children who died under one year was 48; the number under five years, 67. The number of persons who died over sixty years of age was 54. The deaths in public institutions were 95.

Cerebrospinal meningitis, 1 case and 1 death.

Of the above infectious diseases the following were non-residents: Consumption, 17 cases and 3 deaths. Scarlet fever, 2 cases.

Deducting deaths of non-residents, the total is 191 and the death-rate is then 15.81.

TESTING ICE CREAM CONES. — The health commissioners of Boston have investigated the ice cream cones, popular in certain parts of the city, with reference to the presence of poisonous substances, but, it is stated, with negative results.

AWARD OF THE WARREN TRIENNIAL PRIZE. — The Warren Triennial Prize for 1910, of $500, has been awarded to Dr. George H. Whipple, Johns Hopkins Hospital, Baltimore, Md., for an essay entitled "The Pathogenesis of Icterus."

MORE MILK TROUBLE. — The publication by the Boston & Maine Railroad of new freight rates for milk transportation, by making the city

contractors pay higher rates, seems likely to deprive Massachusetts farmers of several cents a can. The farmers are sending to Governor Draper a petition to set aside the Saunders milk bill, which they hold to be responsible for the new rates.

NEW YORK.

A CENTENARIAN. — On July 4, Josiah Zeitlein, of Brooklyn, N. Y., celebrated the supposed one hundred and sixth anniversary of his birth. He is said to have been born in 1804, at Lodz, Poland. He came to the United States in 1886. It is said that his health is excellent and that he intends soon to take up the study of the English language, which he has never yet learned.

MORTALITY STATISTICS. — The weekly reports of the Health Department show that during the month of June the mortality in the city represented an annual death-rate of 15.43, as against 16.11 in May and 15.20 in June, 1909. In most diseases there was a falling off in fatality. The weekly average of deaths from measles declined from 21.5 in May to 20.25 in June; the weekly average from scarlet fever, from 23.75 to 18.5; from whooping cough, from 8 to 5.75; from diphtheria and croup, from 42 to 35.25; from influenza, from 6 to 3; from epidemic cerebrospinal meningitis, from 7.75 to 5.75; from pulmonary tuberculosis, from 175 to 154.25; from pneumonia, from 111.75 to 67.5; from bronchopneumonia, from 95 to 73; from cancer, from 73.75 to 70.25; from apoplexy and softening of the brain, from 23.75 to 17.25; from organic heart diseases, from 127.25 to 126.75; from cirrhosis of the liver, from 22.25 to 20.75; from Bright's disease and acute nephritis, from 108.25 to 106.75; and from puerperal diseases, including septicemia, from 14.75 to 13.75. Among the few diseases in which there was an augmented fatality were the following: The weekly average of deaths from typhoid fever increased from 8.25 to 9.5; from acute bronchitis, from 14 to 16.25; from appendicitis and typhlitis, from 11 to 14; from diarrheal diseases, from 61.25 to 131; and from diarrheals under five years of age, from 55.25 to 122. It is rather discouraging to find that, notwithstanding the increased systematic efforts to control the mortality from summer diarrhea of infants, the number of deaths from this cause is considerably larger than at the same season last year. Thus, in the last two weeks of June, 1909, the deaths from diarrheal diseases in children under five years of age were respectively 86 and 120, while in the corresponding weeks this year they were 136 and 186. The existing meteorological conditions, no doubt, had something to do with this result. During the month one death from smallpox was reported. The corrected death-rate, excluding non-residents and infants under one week old, was 14.50.

1. The chief points in Abbe's very interesting review of Tyrar's experience with the use of radium in surgical diseases are as follows: Radium is comprised of variously active rays, — *alpha*, *beta* and *gamma* rays. The *alpha* rays have no therapeutic value and are cut off by the use of a lead screen. *Beta* rays are the most potent. *Gamma* rays penetrate most swiftly and deeply, but carry no electricity. The theory is that the rays not only penetrate the diseased structures, but also give off something of themselves which remains to act on the tissues long after the initial application. They inhibit growth or devitalize tissue proportionately to their time exposure. The success of treatment depends largely on the nicety of the time exposure. Germs are markedly altered in virulence by exposure to the rays, becoming less virulent. What has been accomplished in epitheliomas of all grades, ulcerated or not, when situated on the skin, is that a healing and disappearance of the growth promptly follows a correct dosage. So far, cancer of the lip and of all mucous surfaces has resisted this treatment. No cases of lip cancer have been cured. Non-malignant papillomata of the tongue have been cured in four cases. Retrograde changes have occurred in the tumors of the mouth, but have not lasted long. Cancers of other regions have suffered some retardation, but nothing more. Selective action has been witnessed in round-cell and giant-cell sarcoma, and several cures have resulted.

2. Knowles summarizes as follows: Purpuric eruptions caused by ingestion of the iodides may be divided into two groups: (1) That with extensive petechial and hemorrhagic bullous cases, which occur in organic diseases of the kidneys or heart or with lowered general condition, or in idiosyncracy for the drug. (2) That with localized distribution, especially on the lower extremities in perfectly healthy individuals. In the bullous type the face and extremities are particularly involved. Mild symptoms of iodism are present in a few cases. Severe reaction may occur and even edema of the glottis. Hemorrhages occur from the mucous membranes. The various salts of iodin

are all capable of causing a purpuric eruption. The pathologic changes of the skin were noted in the immediate vicinity of the blood vessels and in the walls of the vessels themselves. Iodin is rapidly absorbed by all mucous and serous surfaces and rapidly eliminated, chiefly by the kidneys. The leucocytes play a distinct rôle in the absorption of the drug. Hemorrhagic cases of extensive distribution of the bullous type are often fatal. Non-bullous types rarely terminate fatally. [E. H. R.

1. Morse and Talbot call attention to the general lack of attention to caloric needs in the feeding of children and to the usefulness of examination of the stools in determining what classes of foods are being ingested in excess of the powers of digestion and assimilation. The caloric and protein needs of children are not exactly known, but, according to the best evidence at our command, the normal requirements per twenty-four hours are approximately as follows: At four years, 70 calories and 3.5 gm. of proteid per kgm. of body weight; at eight years, 3.0 gm. proteid and 60 calories per kgm.; at twelve years, 50 calories and 2.5 gm. proteid per kgm. By reference to a table of food values of the ordinary articles in children's diet the feeding is easily regulated according to these figures. In cases of improper feeding and of disordered digestion, evidence of abnormality is furnished by examination of the stools, of which three chief types are mentioned: (1) *Fatty stools*, gray or white in color, dry, clay-like or creamy, acid in reaction and of rancid odor; (2) *carbohydrate stools*, brown or yellow, and, on hasty examination, often apparently normal, but of acid reaction and sour odor; (3) *catarrhal stools*, showing an excess of mucus, often associated with protein putrefaction and foul odor. Simple microscopical examinations further demonstrate the presence of fat, of starch or of mucus in excess. Five illustrative cases are reported where correction of the diet according to the theoretical requirements of the child, further modified by the findings in the stools, led to improvement.

2. Kaufmann maintains that the danger from hemorrhage in gastric ulcer is commonly overrated, the evidence of combined statistics leading him to estimate it as not more than 3%. The bleeding tends to spontaneous arrest, by falling blood-pressure and thrombosis. Stimulation and infusion are to be avoided since they tend only to prolong the hemorrhage. When the bleeding has ceased, recurrence is best avoided by complete rest, with morphine, ice-bag to the epigastrium and temporary cessation of all feeding, contrary to Lenhartz's recent advice, although too prolonged starvation is also to be avoided. If bleeding continues, the old-fashioned styptics are not advised. Even the adrenalin treatment, recently advocated, is not favored. Chief reliance is placed upon the use of bismuth, and of lavage.

3. Welch reports striking results in the treatment of hemophilia neonatorum. Of 18 cases of this disease preceding his series in the same hospital, treated by various methods, 17 died. Of his 12 cases, all were cured. Acting on the supposition that the chief factors which have produced the beneficial effects of transfusion are in the serum, he gave subcutaneous injections of normal human serum, usually 10 ccm., two or more times a day. Blood was aspirated from a vein of the donor into a sterile flask, allowed to coagulate in a slanting position, and the serum collected on separation.

4. Pemberton reports results of a study of metabolism in a case of myasthenia gravis. The most notable findings were an increased elimination of calcium and a diminished creatinin output. The loss of calcium is of special interest on account of the known connection of calcium with muscular metabolism. Calcium lactate was given therapeutically in this case and its use was followed by improvement.

5. Spiller discusses the treatment by resection of posterior nerve roots in cases where spasticity predominates over paralysis, particularly in cases with athetosis. This treatment he first proposed in 1905. The first case in which this procedure was executed was published by Foerster in 1908. Since then 17 cases have been reported by four authors, with one death. Spiller mentions 2 cases operated upon by Frazier on his recommendation, one reported in detail elsewhere.

6. Ewing writes exhaustively upon the various theories and questions regarding the toxemia of pregnancy. He supports the view that the simple and pernicious vomiting, the liver changes from the hemorrhagic hepatitis of eclampsia to acute yellow atrophy, the renal and the nervous manifestations, are all results of essentially the same disorder of metabolism. He believes that the ordinary vomiting of pregnancy is but an early stage of disturbance which may end in fatal hyperemesis, malignant jaundice or acute yellow atrophy or eclampsia. He believes that the disturbance is autotoxic, and guardedly suggests that the intoxication may be at least in part of intestinal origin. He does not accept the theory of placental or fetal source of intoxication. In early diagnosis, he regards increase of ammonia and of rest-nitrogen in the urine as of importance. In prophylaxis and early treatment he advises dietetic measures to overcome acidosis and indicanuria, reduction of proteins, and the intelligent use of thyroid extract.

7. Tileston and Griffin discuss the condition of chronic family jaundice first accurately described by Minkowski in 1900, and hitherto not reported in this country. It is to be inferred, however, that the condition is far from rare, since these authors have been able in a short space of time to investigate four families, in each of which from three to seven members were affected. The disorder is characterized by the occurrence in several members of a family, often of several generations, of a permanent jaundice, dating from birth or from adolescence, without interference with the growth, longevity or comfort of the patient. The icterus is usually not intense and is not accompanied by clay stools. The urine contains urobilin, but no bile. Enlargement of the spleen is almost a constant feature; the liver is usually not enlarged. Autopsies show no obstruction of bile ducts; the jaundice is probably due to an abnormal susceptibility to hemolysis of the red blood corpuscles, with resulting excess of free hemoglobin, out of which bile pigment is made. Thirteen cases are reported in detail, occurring in four families; autopsies are reported in two instances. [F. W. P.]

1. Holt's article contains an account of work he has been doing on the relation of Pfeiffer's bacillus to acute infections of the respiratory tract in children. The report is preliminary to further work along the same line. He believes that the term "influenza" should be limited to an inflammation or infection excited by Pfeiffer's bacillus; that this bacillus is of great importance in all infections of the lower respiratory tract, expecially in cold weather, but that it has very much less to do with acute nasopharyngeal catarrhs and their complications, otitis, adenitis, etc. It may cause severe general symptoms, with few or no local symptoms, even of the respiratory tract; but general blood infection with this organism is very rare. While in most patients the influenza infection causes acute symptoms only, recurrences are exceedingly common, and in some patients the attacks are prolonged, persisting for months. The B. influenzæ may be harbored in the secretions of apparently healthy persons for a considerable period, certainly for several weeks; whether such persons may spread the disease is not certain. If properly made, cultures are of great value for diagnosis, but the bronchial secretions should be secured.

2. Rose recommends a method for the clinical estimation of pepsin. He uses, instead of a solution of ricin, as is used in the Jacoby-Solms method, a solution of globulin obtained from the ordinary garden pea. He gives explicit directions as to the preparation of this globulin solution. He also modifies the older method by making all digestions in a solution of the same acidity (0.2% hydrochloric acid). In this way one determines, not the digestive power of the gastric fluid, but the relative amount of pepsin present. The method has distinct advantages over the ricin method, in that the globulin solution can be depended on to be pure, and the acidity is always constant.

3. The authors report further experimental work along the lines of interglandular correlation. They find that the inhibition of pancreatic activity by adrenalin and pituitary extract is independent of the systemic blood-pressure, as shown by its persistence when the blood-pressure is much below normal, and by other evidence. The inhibition by extracts of pituitary and super-renal bodies also occurs when the pancreas is stimulated by its normal excitant, hydrochloric acid, in the duodenum. In dogs rendered diabetic by extirpation of the pancreas, the mucosa of the duodenum remains abundant, in striking contrast to the emaciation of the other tissues, and acid extracts of the mucosa are as active as, if not more so than, those from normal animals. Their studies on the activity of pancreatic secretion (when excited by secretin) and of the inhibition of pancreatic flow by adrenalin in thyreoparathyroidectomized dogs have indicated no clear departure from the normal in this regard. This is probably also true of dogs the subjects of thyroidectomy alone.

4. In cerebrospinal meningitis the author finds heightened intracranial pressure to be an almost constant phenomenon, and heightened blood-pressure of a moderate degree is not infrequently seen in the early acute stages, when exacerbations of the symptoms occur late in the disease, or when the malady takes on a chronic aspect. The blood-pressure seems to bear some relation to the severity of the disease, being higher when the symptoms are severe, and lower during convalescence. The withdrawal of cerebrospinal fluid by lumbar puncture has no constant effect on blood-pressure, although there is usually a fall of blood-pressure synchronous with this procedure. The series of observations affords no definite evidence that a heightened intracranial tension causes an increased blood-pressure in meningitis.

5. Hooker gives a critical review of the opinions expressed concerning the question of postural or orthostatic albuminuria. He appends a complete bibliography of work on the subject. He favors the view that the causation of this condition is probably to be explained by a vasomotor instability. He notes the relation of this condition to variations in the pulse pressure, the albumin appearing with the lowered pressure and disappearing again when the pulse pressure reached normal. The consensus of opinion seems to be that orthostatic albuminuria is not necessarily directly associated with a permanent impairment of renal function.

6. The article contains the report of a case of cholecystitis where the paratyphoid Bacillus A was proved to be the underlying cause. The author gives a summary of the articles which have appeared on the subject.

7. The authors report a case where the giving of pituitary extract produced marked improvement in a case of infantilism. They give at length their reasons for making the diagnosis of pituitary tumor.

6. *Woolsey, G. *Post-Operative Intestinal Obstruction.*

1. Ely, on joint tuberculosis, advances new and interesting theories. He does not agree with Nichols, of Boston, who believes that all joint tuberculosis originates in a bony focus, but holds that there are two places from which it may originate: First, in the red marrow of the bones, and, second, in the synovia. A tuberculous focus spreading in the marrow may find its way directly to the periosteum, and, breaking through this, may form an abscess in the surrounding tissues and so reach the surface without ever involving the joint. But in the majority of cases it goes through to the joint. No serious damage is ever done to the joint cartilage in tuberculous disease except that which is done indirectly by involvement of the bone marrow beneath it. In many cases a smooth cartilage will give no idea of extensive bone disease beneath it. The pathology of the whole process shows nature's effort to abolish function. This teaches what the treatment should be. The disease is cured, not by extensive dissection of diseased bone and soft parts, but merely by securing ankylosis. Some interesting illustrative cases are reported. This is radical treatment, but seems well backed up by the cases.

6. Woolsey deals exhaustively with post-operative intestinal obstruction. Points emphasized are as follows: The majority of cases do not occur within two weeks, as stated by others, but the author found 70% occurred after two weeks. The late cases are all of mechanical origin; the early cases may be mechanical or paralytic. Paralytic obstruction is most often but not invariably due to sepsis. The commonest form of mechanical obstruction depends on a kinking or angulation of a loop of gut due to its adhesion to the parietes or another loop. The small intestine is the part involved in 95% of the cases. The Trendelenburg position may be a cause of obstruction. Paralytic obstruction may be due to sepsis, handling, or disturbance of the nerve supply to the intestine. [E. H. R.]

2. The finding of tubercle bacilli in the circulating blood was described in this country by Rosenberger and Liebermeister a few years ago. Following that many pieces of work were done tending to show that the observations of these authors depended on bacilli other than the tubercle bacilli. Jessen and Rabinowitsch now report on 36 cases of different severity of tuberculosis and find tubercle bacilli in the blood of a considerable number of them. Upon studying their cases they find the bacilli present full as frequently in the mild as the severe cases, and, therefore, conclude that their presence in a demonstrable amount in the blood stream is no indication of the severity of the infection. 2. Hirschfeld quotes from cases of his own and of other observers on the frequency of glycosuria, and also the possible severity of diabetes in pregnancy. Careful observers note about 10% of all pregnancies to be complicated by glycosuria. A great proportion of these go through their pregnancy, labor and puerperium without any serious complications, delivering a normally developed child. In spite of this, the author considers that in no case can one be assured of the prognosis, as the lightest and most favorable case of glycosuria may develop into the severest form of diabetes. He finds that glycosuria is of more significance when it appears in the third or fourth month of the pregnancy. Diabetic coma is rare in even the severer cases. He emphasizes the importance of not attempting to place a boundary line between diabetes and the glycosuria of pregnancy without serious consequences. [J. L. H.]

REVUE DE MÉDÉCINE.

MAY, 1910.

1. *LÉON, BERNARD. *The Nature of Osteomalacia.*
2. DEVIC AND LAVY. *Mediastinal Pleurisies. First Chapter.*
3. JOB AND FROMENT. *Acute Poliomyelitis. Second Chapter.*
4. *BERTIN AND GAYET. *The Wassermann Reaction in Hereditary Syphilis.*
5. JOB AND FROMENT. *Acute Poliomyelitis. Third Chapter.*

1. The nature of this disease has been the cause of great doubt at all times. Chemical disturbances of the gastro-enteric tract have been cited as etiological factors; and the ovaries, the thyroid and the suprarenals have been successively, if not successfully, accused. The production of the disease experimentally by animal inoculation throws a different light upon the subject at the present time. The authors advance the theory that, under certain influences, the marrow, which has been irritated, shows a "reaction." This is evidenced by congestion, which may go on to hemorrhage, and by cellular proliferation. The latter effects the blood elements less than the "osteopoietic" side. The latter reaction gives rise to the cells "ostéoblastigues et myéloplaxies," which participate in the process of decalcification. It is understood thus that the irritation of the marrow gives rise to osteomalacia only because of the participation of these "osteopoietic substances." It is a theory most attractive, but as yet not proven.

4. From the study of a long series of cases the authors conclude that a positive Wassermann reaction is present in all positive cases of syphilis and is absent in those giving no stigmata of the disease; furthermore, that it is never found in cases not infected with syphilis, except in a few instances where the disease is strikingly different, i. e., scarlet fever and leprosy. Inasmuch as the reaction persists much longer than most or even all of the clinical signs, its diagnostic value is easily understood. [L. H. S.]

June, 1910.

1. Solomon and Halbron. *The Reaction of the Islands of Langerhans and the Lymphoid Organs to Experimental Inoculation of Tubercle Bacilli.*
2. Devic and Lavy. *Mediastinal Pleurisies. Second Chapter.*
3. *Job and Froment. *Acute Poliomyelitis. Fourth Chapter.*
4. Devic and Lavy. *Mediastinal Pleurisies. Third Chapter.*

3. In conclusion, the authors affirm the belief in the identity of epidemic poliomyelitis with acute sporadic spinal paralysis. Anatomically and clinically this is essentially true, but the clinching argument would lie in the identity of their etiological factors. Unfortunately this proof cannot be given at the present time, although there is reasonable hope for it in the near future. A most complete bibliography is appended to the last chapter of the series. [L. H. S.]

Correspondence.

AN APPRECIATION OF THE SEA.

On Board S.S. Zeeland, 1 July, 1910,

Lat.: 41° 4′ N. Long.: 47° W.

It might seem that the mid-Atlantic, especially the "roaring forties," were hardly an auspicious or opportune place for medical observation or improvement. Yet in point of fact, a physician can sit upon the deck of a deep-seagoing ship and view the works of creation with as much pleasure and profit as in his own office ashore. For not only does such a ship afford him nearly all the interesting objects of contemplation that he finds on land, but the ocean itself is as rich with appropriate and unfamiliar suggestion

> "As is the ooze and bottom of the sea
> With sunken wrack and sumless treasuries."

First of all, there is the ever-present and pertinent subject of seasickness, or rather, shipsickness, nausea, an ailment so ancient and honorable that it has a genuine Greek name, not a hybrid Latin one in *-itis*. Many speculations, popular and scientific, have been made as to the exact nature and cause of seasickness. It seems to affect chiefly women, "the kind of man called a clergyman," and others of a neuropathologic diathesis. It presents itself under several clinical types. First, there is the purely imaginary type, in which the patient, usually a robust chronic invalid with plenty of money, is perfectly sure in advance that she will be sick, takes to her bunk before the ship sails, has all the delicacies of the saloon brought to her stateroom by a sympathetic stewardess, and reappears, on landing-day, sleek, plump and rosy, with voluble comments on the horrible voyage. In such cases there is no remedy. Second, there is the bilious type, with headache and some nausea, chiefly affecting the soulful, dyspeptic curate, the fat old lady with gallstones, the thin, sallow co-ed, and other victims of chronic constipation. Here the remedy is obvious. A sub-variety under this group is characterized solely by occipital headache and seems probably due to unwonted eyestrain or ocular fatigue from glare, or possibly to the necessity of unaccustomed and continuous cerebellar co-ordination. The remedy in such cases is, of course, rest and suitable protection of the eyes. The third type is that due solely to excess at table, or in the smoking-room, usually affects men, is accompanied by profuse emesis, and proves self-limited unless a future attack is induced by repeated indulgence. In short, seasickness is not a definite disease, but a symptom-complex, more often central than peripheral in origin, and due to the concurrence of various disturbing factors, often operative separately on land, without harm, but capable, when occurring together, of upsetting the gastric equilibrium of persons functionally predisposed to such instability. There are some people who are seasick under all conditions, and some who are never seasick under any conditions. For those who fall in the intermediate class, the chief precautions advisable seem to be discretion in diet, abundance of fresh air and exercise, free cartharsis, and great temperance in the use of alcohol and tobacco, rules of hygiene which might well be made general. It is perhaps needless to add that the writer of the present lines has never yet been seasick.

Apart from such medical observations as the above, and other general diagnostic speculations in which a physician is prone to indulge even when contemplating his fellow-men socially, one is dependent for his direct professional converse and pabulum on the ship's doctor. The surgeon on this boat is a shrewd, genial young Irishman, who has served in the army, too, and avers that there is no money in the profession on land or sea, but that, like the "tramp royal," and, indeed, like all of us for that matter, he "couldn't quit it if he tried." He took us over the ship with him on inspection, showed us the sanitary and culinary accommodations of the steerage, which are excellent, and finally his surgery, — "a poor thing, but mine own," he apologised needlessly, — for the hospital, though small, was admirably equipped, and the instrument case contained almost all the heart could desire. Hopes for a possible appendectomy aboard, however, seem likely to be thwarted, for, as he says, "One is seldom really sick at sea." It is strange how quickly the normal professional reflexes recur; and though one leave shore heartily sick of patients and hospitals, in two days one is hungry for the smell of ether, and gravitates, with the usual clannishness of our kind, to the association of another physician. It is pleasant to walk and talk and smoke with the doctor on the forward deck after dinner, hear his tales of South Africa, learn his opinions of vaccine therapy and medical education, play chess with him, and listen to his comments on people and things in "The States" and elsewhere.

When the doctor is busy, and one is tired of observing one's fellow passengers, or has momentarily exhausted the interest, always keenest on shipboard, afforded by one's own physiology, one can always revert for solace and occupation to the sea, the oldest, most inscrutable of natural objects, the primal origin and home of all forms of life. Aside from its literary, romantic and esthetic connotations, and its actual, ever-varying beauties of form and color, the ocean is a reservoir of limitless suggestion to speculation in the sciences. As one stands at the prow, watching the ruck of clouds above, or the white scud at the parting of the waters beneath, the sun and the passing ships by day, the white sea-horses that rear their manes of flying foam to race alongside, the clustered brilliancy of the stars and the Milky Way at night, the marvel of man's knowledge and dominance becomes almost miraculous. That the high development and exquisite adaptation of his central nervous system have made possible this dominion over the beasts of the field, and the fowls of the air, and whatsoever passeth through the paths of the sea, seems the biologic conclusion. And one is tempted, from his position at the prow of life, to trace his being through known and unknown forms of animate existence, past his cousins that have remained, — the gull that sweeps and circles overhead, whose problems of aviation man has just begun to solve, the dolphins that dive and dash at the bow, the lazy squid that lolls its jelly-like mass and tentacular arms, the phosphorescent animalcules that make the waters glow alongside at night, — back to the ultimate ooze of the sea from which emerged the primordial animal cell. It makes the still marine cells of one's organism rejoice to be thus brought into closer kinship with the past along this perspective of their pelagic ancestry, and one's epidermis and respiratory epithelium are healed by restoration to the normal saline which pervades even the air at sea. Perhaps such speculations are fantastic. Howbeit, they serve to show that wherever there is life, there is interest and opportunity for the physician, to whom even that which is not human is never alien, for his profession is the application of all knowledge to the problems of human living.

Medicus Peregrinus.

LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND OTHER OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED JULY 6, 1910.

KERR, J. W., assistant surgeon-general. Granted one month's leave of absence from July 7, 1910.

LONG, J. D., assistant surgeon-general. Directed to proceed to Columbus, Ga., upon special temporary duty. June 27, 1910.

MCINTOSH, W. P., surgeon. Granted four days' leave of absence from July 5, 1910.

NYDEGGER, J. A., surgeon. Granted seven days' leave of absence from July 3, 1910.

GRUBBS, S. B., passed assistant surgeon. Granted four days' leave of absence en route to station.

LUMSDEN, L. L., passed assistant surgeon. Directed to proceed to Norfolk, Va., upon special temporary duty. June 24, 1910.

ANDERSON, JOHN F., passed assistant surgeon. Granted five days' leave of absence from July 5, 1910, under paragraph 189, Service Regulations.

LEAKE, J. P., assistant surgeon. Granted seven days' leave of absence from June 24, 1910, under paragraph 191, Service Regulations.

ALTREE, G. H., acting assistant surgeon. Granted thirty days' extension of leave of absence from May 3, 1910, on account of sickness.

DUFFY, FRANCIS, acting assistant surgeon. Granted four days' leave of absence from July 6, 1910.

HOUGHTON, M. W., acting assistant surgeon. Granted two days' leave of absence from July 2, 1910.

MORGAN, ROY, acting assistant surgeon. Granted seven days' leave of absence in June, 1910, under paragraph 210, Service Regulations.

STEWART, W. J. S., acting assistant surgeon. Granted one month's leave of absence without pay from June 23, 1910.

STORY, HENRY C., acting assistant surgeon. Granted thirty days' leave of absence from July 1, 1910.

WALKER, T. D., acting assistant surgeon. Granted eleven days' leave of absence from June 28, 1910.

WETMORE, W. O., acting assistant surgeon. Granted five days' leave of absence from June 8, 1910, and one day's leave of absence, June 15, 1910, under paragraph 210, Service Regulations.

MACDOWELL, W. F., pharmacist. Granted one day's leave of absence, June 9, 1910, under paragraph 210, Service Regulations.

IRWIN, CHARLES H., pharmacist. Relieved from duty at Chicago, Ill., and directed to proceed to Angel Island Quarantine, Cal., and report to the medical officer in command for duty and assignment to quarters. July 1, 1910.

CASUALTY.

MASON, M. R., pharmacist. Died June 29, 1910.

CHANGES IN THE MEDICAL CORPS U. S. NAVY DURING THE WEEK ENDING JULY 16, 1910.

BERRYHILL, T. A., medical inspector. Commissioned medical inspector from March 5, 1910. July 12.

SEAMAN, W., surgeon. Commissioned surgeon from Dec. 13, 1909. July 13.

RICHARDSON, R. R., surgeon. Commissioned surgeon from Jan. 30, 1910. July 13.

DUNN, H. A., surgeon. Commissioned surgeon from Feb. 19, 1910. July 13.

STUART, A., surgeon. Commissioned surgeon from March 5, 1910. July 13.

STEPP, J., surgeon. Commissioned surgeon from March 24, 1910. July 13.

SHORT, W. H., passed assistant surgeon. Commissioned passed assistant surgeon from May 4, 1910. July 13.

PHILIPS, E. W., assistant surgeon. Detached from the "Marietta" and ordered to continue treatment at the Naval Hospital, Portsmouth, N. H. July 13.

IRVINE, W. L., assistant surgeon. Detached from the Naval Training Station, Newport, R. I., and ordered to the "Marietta." July 13.

STRINE, F. S., passed assistant surgeon. Detached from the Naval Hospital, Olongapo, P. I., and en route home. July 14.

BROWN, H. S., passed assistant surgeon. Detached from the Naval Hospital, Canacao, P. I., and ordered to duty at the Naval Hospital, Olongapo, P. I. July 14.

SOCIETY NOTICE.

AMERICAN PUBLIC HEALTH ASSOCIATION.—The American Public Health Association will hold its thirty-eighth annual meeting in Milwaukee, Wis., Sept. 5 to 9 next. Representatives from many of the national organizations working in the interest of the public health have been invited to be present and to discuss methods for the correlation of the work of such organizations, and for co-operation with a view to increasing efficiency and economy. Sanitary engineering will occupy a conspicuous place on the program. This Association is the oldest national sanitary organization in the United States. Its membership extends over the United States, the Dominion of Canada, Mexico and Cuba. Information concerning it can be obtained by addressing Dr. Wm. C. Woodward, Secretary, Washington, D. C.

RECENT DEATH.

DR. LESLIE DODD WARD, of Newark, N. J., died in London on July 13. His family were among the first settlers in Connecticut, and subsequently moved to New Jersey, where they were among the founders of the city of Newark in 1666. He was born in Madison, N. J., on July 1, 1845, and during the Civil War he left the Newark Academy to serve as an officer in the 37th Regiment of New Jersey Volunteers. After the war he studied medicine and was graduated from the College of Physicians and Surgeons, New York, in 1868. He practised with much success in Newark, and for many years was county physician of Essex County. In 1874 he helped to found the Prudential Life Insurance Company, and was appointed its medical director. In 1884 he was elected first vice-president of the company, a position which he still retained at the time of his death. Dr. Ward was well known for his interest in art, his knowledge of which was extensive. He was president of the commission in charge of the erection of the Essex County court house in Newark, which was completed about four years ago at an expense of $2,000,000. The elaborate decorations of both the exterior and interior were chiefly the result of his suggestion and work. He had fine collections of paintings at his home in Newark and his country residence at Brooklake Farms, near Madison, and also a very valuable private library.

GYNECOLOGICAL OPERATIONS ON NEURASTHENICS. ADVANTAGES, DISADVANTAGES. SELECTION OF CASES.*

BY EDWARD REYNOLDS, M.D. BOSTON.

At the outset of any paper upon this subject the term "neurasthenia" should be defined in the sense in which it is to be used throughout the the paper, since its mere definition has provoked in the last ten years a large neurological literature of its own, and is still unsettled. The word "neurasthenia" is, in fact, like the word "rheumatism," one which covers so many different states as to have no satisfactory meaning in modern medicine. For our present purposes this loose and popular term may be defined as implying merely a state of low resistance to the depressing influences of the environment, irrespective of the cause to which this low resistance may be due. When the term is used in this sense it follows as a logical necessity that the first point of importance in the management of neurasthenia is the classification in accordance with its cause, and since this must be determined by symptomatology, we may say at the start that success in the treatment of neurasthenia complicated by pelvic lesions depends primarily upon the exactitude of our knowledge of the importance of symptoms.

It is a common statement that gynecological diagnosis is rendered difficult to the mass of practitioners from the fact that facility in the pelvic touch can only be obtained by a large experience and constant practice. I became convinced some years ago that the majority of mistaken diagnoses which I see were so mistaken less from the practitioner's inexpertness of touch than from his having relied too exclusively upon this method of physical examination, and neglected the study of symptomatology, to which he would have turned instinctively in any other than a gynecological case.

Since then I have watched my practice now for a good many years with this point in view. I have certainly noticed that the gentlemen whose cases habitually come to me with a correct diagnosis almost invariably refer to the symptomatology, and often to the symptomatology only, in describing the case, while those whose diagnoses frequently seem to me incorrect usually give me no account of the case other than their physical examination. This is to me a somewhat suggestive observation; moreover, after a good many years' experience with the touch I feel that, for me, diagnosis in gynecological cases rests quite as much upon symptomatology as upon the pelvic examination, or, more exactly, that the latter gives only a diagnosis of physical state which is worthless for therapeutic purposes until it has been interpreted by the accompanying symptomatology. In addition, while I believe that the anatomic condition must be ascertained by the touch, I believe also that the determination of the treatment which should be adopted depends far more upon the symptomatology than upon the pelvic examination, and that this fact is far too little appreciated.

There is one other point of great importance in this connection to which I must refer. In this branch of medicine, as in all others, we are far too ready to be satisfied with the mere process of giving a name to the patient's condition. We too seldom proceed to the further but much more useful step of attempting to determine why that condition appeared. We forget the fact that, until we have learned the cause of the condition to which we are able to give a name, we have learned little or nothing of what will most readily relieve it.

I believe that the emphasis of these two points, the value of symptomatology and the importance of the search for the ultimate cause, will by itself do more to save us from mistakes of diagnosis and treatment than any other one thing, and, further, that it will enable us to bring to prompt relief many chronic cases which would otherwise linger along under unsatisfactory palliation.

In the differences of opinion which so frequently occur in the management of neurasthenics with chronic surgical affections, the truth probably lies midway between the failure of many surgical specialists to realize the presence and sometimes the dominating importance of neurasthenia in their cases; and, on the other hand, the equally grave failure of many neurologists and general practitioners to realize the presence and at least contributing importance of local lesions in the same cases. In fact, both elements are present in varying degrees of importance in most (but not all) neurasthenias.

Neurasthenics vary all the way between the extreme neurotics, who are always to have exaggerated symptoms from a succession of absolutely trifling local lesions, to the more hopeful class of cases in whom the nervous instability originally only potentially present has been developed by an acquired and curable local lesion.

In the first class of intractable neurotics, local treatment, whether operative or minor, usually only fixes the attention of the patient and increases the evil. If we could insist on the avoidance of operation in these cases we should do away with the disastrous cases which every one has seen, in which an operation has resulted in making a complete nervous wreck of the patient. These operations are disastrous not because the patient was a neurotic, but because she was operated on for a condition which had nothing to do with her neurasthenia. Unnecessary operations usually do physical harm, and when to the nervous fatigue which in a greater or less degree follows all operative work we add the failure of relief from so important an effort, it is no wonder if a previously unstable neurotic is made permanently worse instead of better.

In the second class, in whom the neurasthenia is plainly secondary to the depressing effects of a local lesion, general treatment, if relied upon

* Read before the Norfolk District Medical Society, Nov. 30, 1900.

alone, only gives the local lesion time to develop, to become important, and, perhaps, in the end, to develop the neurasthenia to a degree which may even be self-sustaining after the relief of its original cause; in these cases the cure of the local lesion is not the cure of the neurasthenia, but it is a necessary preliminary to the cure of the neurasthenia by nature under the influence of general hygiene.

Between these two extremes all shades exist, and the practical difficulty in the determination of the treatment appropriate to individual cases in the middle of the series is often so great as to result in the many failures of wisdom which we see. I believe that it is essentially failure to appreciate the radical difference between these two classes which gives rise to the extremes of opinion which are put forth so acrimoniously.

Although the subject is so complicated that in it results must always depend upon the clinical wisdom of the individual practitioner, three general principles have been of the greatest value to me in this most difficult department of the art of practice.[1]

These three principles are

A. Neurasthenias in which local lesions are of importance always involve the presence of persistent local symptoms.

B. Careful, extremely careful, study of the chronological sequence between the general and local symptomatologies is of prime importance in determining the etiology of the neurasthenia.[2]

C. In neurasthenic women with pelvic lesions frequent and long-continued office treatments may relieve the local symptoms or even the lesion, but usually, if not always, increase the neurasthenia to a degree which makes the patient as a whole worse and not better for our care; further, properly selected neurasthenic cases usually do well under reparative operations, but, with the exception of those dependent upon new growths, are usually injured by the radical removals.

The art of application of these principles is difficult, but I think that the principles always apply. Their observation will at all events lead to an avoidance of the disastrous failures of special surgical treatment which are so common among us.

Though the specialist may overestimate the importance of local lesions, yet, as has been said, the general practitioner is far too apt to neglect the localized symptoms of neurasthenics. The general constitutional view comes first, but after the institution of the all-important general treatment, the first step towards forming a final opinion of a neurasthenic case should lie in determining the presence or absence of any localized affection of importance, and the first step in this direction should be a careful inquiry into the symptomatology, but in this connection it should be noted at the outset that more weight should be given to the persistence and unvarying character than to the severity of the local symptoms.

[1] The art as opposed to the science of medicine.

[2] These two principles apply to the entire subject of local treatment in neurasthenia; the third is more peculiarly gynecological.

Neurasthenics often complain actively of symptoms which are essentially imaginary, but when a localized symptom has persisted without essential change for several years it has usually a physical cause, and a logical conjunction of several symptoms of moderate severity is always more significant than the comparatively transient complaints which such patients regard as most important and which they often make much the most prominent in their story. Such patients usually complain loudly of transient symptoms which the practitioner at once perceives to be nonsense, and this is apt to distract his attention from less prominent but persistent symptoms which have real etiological significance.

The symptomatology complained of should, moreover, be estimated with the utmost care in connection with the known effect of the lesions which are found. There is no more common mistake in practice than the association of accidental pelvic abnormalities with symptoms to which they have no relation whatsoever. The physician should make himself familiar with the several symptoms to which each pelvic lesion may give rise, and should be cautious to estimate the importance of the anatomical conditions which he finds only in connection with their power of producing the symptoms which are complained of.

I believe that there is no better habit for the consultant than that which I learned from one of my elders, and have followed for many years, of always writing down a provisional diagnosis from symptomatology before making a physical examination. If, then, the provisional diagnosis from symptomatology coincides with the physical state found by the touch, the diagnosis may ordinarily be considered assured, provided that it explains all of the symptoms; but if the diagnoses from symptomatology and the touch do not agree, or if there are still symptoms which are unexplained by the conditions found, all diagnosis should be reserved till further research brings a more consistent explanation.

This is an all-important rule which is essential to a full comprehension of any case, but which we are too often tempted to pass over, almost invariably to our own and the patient's subsequent injury.

Even when the existence of a local lesion which is causing symptoms has been satisfactorily demonstrated, there remains, in neurasthenic cases, the second equally important step of determining whether the local affection can be fairly charged with either the production or maintenance of the neurasthenia, or with any important share therein. On this point I have usually found the chronological sequence of symptoms to be our best guide.

In the absence of a reasonably close chronological sequence between the general and local symptoms, local treatment should be held at least in abeyance, but when a study of the chronological sequence in which the symptoms have followed each other shows either that the neurasthenic condition appeared originally soon after the appearance of

definite and continued local suffering, or that the neurasthenic symptoms have waxed and waned in concurrence with, or in sequence to, the increases and decreases of local suffering, we may safely conclude that a permanent local cure will give general hygienic care the opportunity of effecting a similarly permanent relief of the neurasthenia to such extent as the original constitution of the patient permits. We cannot expect to make constitutional neurasthenics into highly resistant individuals, but we may expect to restore them to the degree of health that they originally possessed, and that is quite enough to satisfy most of them.

Cases in which general care has given only temporary palliative results during the presence of a curable lesion will be permanently benefited or cured by a continuance of the same care after the relief of the local lesion provided it was causative, not otherwise. Having, then, settled by careful study that the local lesion is causative in a given case, it is imperative that one further question should be equally carefully studied before any treatment is undertaken.

Is the local lesion susceptible of definite cure? If not, the neurasthenia will probably be more or less incurable and can be best palliated by general care alone, for, in gynecological work especially, it must never be forgotten that prolonged minor teatment is, in the long run, bad for neurasthenics.

If the local lesion is curable it should be treated by operative rather than minor, and by reparative rather than radical, methods. Modern surgery interferes surprisingly little with the vital processes, and from the standpoint of mortality and mere surgical convalescence, neurasthenics endure aseptic operation entirely satisfactorily. The all-important question with them especially is not the mere surgical recovery, but the remote effect, and that depends in my experience entirely upon the selection of cases and the adaptation of the form of operation chosen to the symptoms involved.

The radical removal of the pelvic organs is, in my experience, of benefit to neurasthenic symptoms only in women who are past the menopause and in whom nature's effort to remove the organs has been arrested by the presence of lesions which prevent their physiological decrease in size. Here radical removals sometimes do good; in other cases they are usually productive only of harm.

In young women our effort should be to remove the disease without injuring the organs, and the extent to which this is now possible is too little appreciated by many of those who are not directly concerned with gynecological operating.

When a local lesion is the exciting cause of a neurasthenia, and can be set entirely right by a reparative operation, the final results are among the most gratifying with which we ever meet, but even in these cases we must never forget that the operative treatment of the local lesion by itself rarely dissipates neurasthenia of any considerable degree. It merely alters the condition by the removal of the cause, so that the absolutely essential, general treatment proper to neurasthenia is likely to become curative where it was formerly palliative. Satisfactory as are the results of a complete and final cure of a causative local lesion as the starting point in the treatment of a neurasthenia, it must, then, be remembered that such success means, not only that the local lesion was really causative, but also that it was susceptible of cure by operation.

Since neither the time at our disposal nor the patience of an audience permits the recital of long lists of cases, I propose to conclude by mere outline reports of a few illustrative cases selected as such from among my records, and as any man whose experience along this line has been at all extensive will find it easy to produce many successful cases, I wish to devote mine mainly to illustration of the points which should be avoided.

A. An operation which fails to effect a final cure usually precipitates an increase of the neurasthenia.

Private Records No. 2201. Sent to me by Dr. A. L. Mason in 1904. Thirty-one years old. Married six months. She had enjoyed exceptional health all her life, without catamenial pain or the avoidance of the most active exercise during her periods. During the congestion incident to recently married life she was subject to excessive fatigue during two successive periods. To summarize the case, from that day to this she has never had a thoroughly painless period. During the succeeding ten months she suffered exceeding catamenial pain, with marked hysteria at these times and steadily increasing neurasthenia. A conservative abdominal operation resulted in the resection of the tubes, both of which were completely occluded; the resection of a large persistent corpus luteum (the so-called solid luteal tumor) from the left ovary and the puncture of numerous follicular cysts therein; right ovary normal. This operation was followed at first by considerable relief of the dysmenorrhea and corresponding general improvement. During the next four years, however, the history was that of variable but on the whole increasing and at times very severe dysmenorrhea, the nervous symptoms varying up and down with the pain, and in the end resulting in marked neurasthenia. In January, 1908, she was operated upon for the second time. The left ovary was found to have been the seat of persistent inflammation, was practically destroyed and surrounded by adhesions. The removal of this ovary, the other being still normal, was followed by almost complete disappearance of the catamenial pain, and a rapid return to good health, though not to quite the exceptional condition which had been hers before she had any trouble.

Though this ovary appeared to be normal, with the exception of a large cyst, it was evidently the seat of an inflammatory process which was beyond the reach of a conservative operation.

Neither the catamenial disturbance, nor the neurasthenia, was benefited by the incomplete operation which was done, but both were promptly relieved by the second operation, which removed all the affected tissue.[3]

B. Prolonged minor treatment often has the worst of effects upon neurasthenics with complicating pelvic ailments, and even an operation may make the nervous condition worse if done in the presence of severe and increasing nervous disturbance.

Private Records 2446. Twenty-nine years old. First came to me in June, 1905, during the prolonged illness of a physician who had been giving her office treatments per vaginam three times a week for about four months, during which time she had been growing steadily more and more nervous. Her uterus lay in left lateral version owing to an inflammatory mass about the left ovary. She was complaining of severe backache, discomfort in the left lower quadrant, and moderate catamenial pain, but her nervous distress and self-centered mental condition were out of all proportion to her other symptoms A moderate-sized pessary for elevation of the cervix gave some relief to the local symptoms, all office treatment was discontinued and the patient was sent into the country under good hygienic conditions for several months, but without benefit. She was if anything in worse nervous condition than before. Her mental condition was extremely distressing. She had become absolutely convinced that her only prospect of health lay in a cure of her local ailments, for which reason, after the complete failure of general treatment, and with her mento-nervous condition growing rapidly worse, I opened her abdomen, broke up numerous adhesions, shortened the utero-ovarian ligaments and suspended the uterus. All local symptoms were relieved, and for a time the nervous condition improved, but after the immediate psychic effect of the operation had disappeared the nervous symptoms became steadily worse, and for a time her mental depression was alarming.

At the time when this patient came to me she had not only been made to devote the greater part of her time for several months to the care of her rather slight pelvic ailments, but as the result of constant and reiterated suggestion had reached a psychic state which almost amounted to a fixed idea. Under these circumstances I thought, and still think, that the operation was imperative; indeed, that it was so is proved by the fact that it did away once and for all with the approach to a fixed idea; i. e., it entirely dissipated the patient's dangerous concentration of mind on her pelvic organs, but the fact remains that the patient's previous bad treatment placed me in a false position for which the patient had to pay the penalty. I have no question that the performance of an operation in the face of an increasing neurosis was the cause of the very distressing psychic condition, amounting almost to melancholia, into which she passed within a few months. It was recovered from in the end, and she is to-day in as good a condition as her native lack of strength is ever likely to permit, but the case illustrates well both the evil effects of prolonged minor treatment and the evil effects of operation under unpromising psychic conditions.

C. We should never forget the importance of subsequent general care and should be guided in our prognosis by our estimate of the possibility of obtaining good and prolonged anti-neurasthenic treatment after operation, under the circumstances of the individual patient's life.

Private Records No. 2745. Sent to me in May, 1907, by Dr. J. H. Knowles, of Gloucester. Thirty years old. Married twelve years. Two children. Neurotic family history. On the whole, good personal health until after marriage and childbirth. Dysmenorrhea, sacral backache, weakness and soreness in lower abdomen, increasingly severe since birth of first child. Now in typical emotional neurasthenia. Provisional diagnosis, accidents of childbirth, not inflammatory. On examination, perineum and cervix lacerated, uterus retroflexed, right appendages probably adherent. Recommended operation. The cervix and perineum were repaired, and the abdomen opened. Conservative of both ovaries, uterus suspended, doubtful appendix removed. The convalescence was satisfactory, the anatomical results were very good, and the patient returned to her home in promising condition. Four months afterwards the anatomical results were equally good, and all pelvic symptoms had been relieved, but to use her own words, she was "nervously no better." On cross examination I learned for the first time that her home life was very fatiguing, living as she did at the head of a household which contained not only her own children, but several of her husband's female relatives. The situation as she described it was enough to prolong any neurasthenia and was at bottom irremediable, but she was lectured on the importance of reserving a portion of every day for exercise out-of-doors and seclusion in her own room, and her physician was urged to enforce these precautions. Under careful observance of this régime she rapidly improved. Six months later she became pregnant again, and when she reported for observation, some months after labor, she declared herself, and appeared, in excellent health. She had escaped with insignificant lacerations and no loss of support. The ovaries were non-palpable.

This case illustrates my failure, and hers, to realize at first that though her pelvic ailments were undoubtedly contributory to her neurasthenia, and maintaining it, if not indeed its original cause, nevertheless prolonged general after-care was quite as important as the due performance of the necessary local repairs. With this added success was fully attained.

D. Neurasthenia of pelvic origin may in some pronounced neurotics become so severe as to persist after the removal of the exciting cause.

Private Records No. 2815. Sent to me by Dr.

[3] It should be noted that from a physiological standpoint the removal of one ovary is not a radical operation.

C. A. Atwood in October, 1907. Thirty-one years old. Five years married. Two children. Coxalgic backache since fall in sitting position when pregnant four years ago; sacral, since puerperium three and a half years ago. For ten years chronic right-sided pain, increased by walking. Family history profoundly tubercular. Was originally a strong girl who trained as a nurse, losing only two days off duty during training, but has been in continued poor health ever since a prolonged suppuration about an ulcerated tooth soon afterwards. Once had a large discharge of pus per anum after a sharp attack of abdominal pain. On cross examination, right-sided pain since this time. Much intestinal indigestion. Profoundly neurasthenic. Is now an inmate of a rest-cure establishment where many months of treatment have failed to do good. Provisional diagnosis uncertain except probably persistence of chronic trouble about an old appendicitis. On examination perineum and cervix lacerated, uterus very low, both ovaries enlarged to about double size, neurasthenia out of proportion to local symptoms, and evidently largely independent of them except that malnutrition and indigestion may be dependent upon with right-sided abdominal condition. After some hesitation operation was advised. The perineum and cervix were repaired. The abdomen was opened. The uterus and ovaries were at the bottom of Douglas' fossa; the ovaries much enlarged, mainly by edema; both ovaries were scarified and cysts punctured, and the uterus was suspended. On turning to the appendix it was found to be the seat of old inflammation lying between the cecum and an adherent coil of small gut, with the canal of which latter it communicated by an old perforation. The appendix was severed from the cecum and separated from the small intestine, the resultant hole in the latter was repaired and the abdomen closed. The patient made an excellent surgical convalescence, the only complication being persistent vomiting, which stopped abruptly and finally on my pretending to be angry with her and giving her a very stern reproof. She went home with every prospect of improvement and for a few months improved steadily, being able to live at home and care for her children and keep her house, but although her home surroundings were satisfactory and her life easy, her vigor was not up even to these demands, she gradually relapsed and has been pretty constantly under the care of a physician ever since. The operation relieved her rather minor local symptoms, but did not materially improve her neurasthenia.

While we are human we shall make mistakes and have our failures no matter how carefully we may study our cases, yet with such study and under the guidance of sound general principles in the selection of individuals these cases will average well.

Private Records No. 2873. Sent to me by Dr. Chandler, of Medford, in January, 1908. Forty years old. Married. No children. Dysmenorrhea always, dyspareunia since marriage. Indigestion with intestinal gas and "sense of goneness" three years. Occasional, not very severe, neuralgia in left sacro-sciatic region, along the distribution of the left sciatic nerve, and over the inner surface of the left thigh, always increased by walking and standing, but almost constant before and during catamenia. Frequent frontal headache. Curetted without relief nine years ago. Pains and aches in all portions of the body. Does not seem in very bad condition, but is very self centered and running from one specialist to another. Provisional diagnosis, orthopedic disability. On examination, pelvic organs normal. Told that she should consult an orthopedist, but that her various specialists should most emphatically be under the control of a neurologist, whom she should see frequently and persistently. Referred to Dr. J. J. Putnam with consent of Dr. Chandler, with written opinion to this effect. Orthopedic treatment under Dr. Putnam's direction proved unsuccessful. Rest-cure under Dr. Putnam's immediate care convinced him that the left-sided pain was genuine and probably of long persistence. At his request examination under anesthesia demonstrated the presence of a slightly enlarged, hard, non-tender left Fallopian tube, and a few days later her abdomen was opened. The left tube proved to be straight and patent, but with much thickened and indurated walls. The corresponding ovary slightly enlarged, sclerotic and containing a very large number of small, tense cysts scattered through it like a charge of birdshot. Left ovary and tube removed. Abdomen closed. Normal convalescence. Patient declares that all abnormal sensations in left side have disappeared. On getting up some left-sided sacro-iliac backache, relieved by therapeutic corset. Returned to Dr. Putnam's care. When last heard from, one year after operation, considered herself well.

This case illustrated well the importance of slight but persistent and annoying local symptoms.

Private Records No. 2678. Patient of Dr. Chamberlin, of Concord. Seen January, 1907. Thirty-eight years old. Married eight years. Two children, last four years ago. Both pregnancies interrupted on account of eclampsia. Previous to childbirth, pessary for retroversion six years. Very gouty family history, very subject to sciatica and other "rheumatic" pains, profoundly neurasthenic and constantly under treatment by one specialist or another. Urine examined monthly by the late Dr. E. S. Wood for nearly three years, and reports preserved find granular and hyaline casts uniformly present. Quantity normal under very free use of liquids, but uric acid always high. After three months' observation with general treatment and occasional local examinations or treatment when absolutely unavoidable, patient had sharp attack of tenderness in the right lower quadrant of the abdomen. On examination two days later right tube slightly enlarged and very tender, purulent secretion coming from os. Says she has had several such

attacks in last few years. A week later pain less, but tenderness persistent till relieved in conjunction with gush of fluid from vagina. Diagnosis of chronic, purulent right-sided salpingitis. In view of persistent renal irritation, constant (gouty?) pain in many places and general neurasthenic degeneration of health, advised operation. Abdomen opened. Right ovary cystic, not much enlarged, right tube occluded, empty, but evidently the seat of both recent and old inflammation; tube and ovary removed. One large follicular cyst in the left ovary removed, uterus suspended, slightly congested appendix removed, abdomen closed. Since operation, now nearly two years, this patient has remained hyperesthetic and subject to many apprehensions, as she probably always will be, and has needed pretty constant supervision, but she is greatly improved in health in every way. Her urine has been examined many times by each of two professional urinologists. The first specimen examined a month after operation contained a few hyaline and fine granular casts. Since then no casts have been found. The purulent vaginal leucorrhea rapidly cleared up after the removal of the tube, and after a few local treatments the resultant cloudy secretion became normal. At the end of a year and a half of persistently normal urine the advice was given that pregnancy might be risked if the patient so chose. She has recently had a normal pregnancy and labor.

Here was a case of constitutional neurasthenia complicated by the existence of a chronic focus of suppuration to which under modern ideas of pathology both the gouty phenomena and renal irritation might fairly be at least in part attributed. With the removal of this center the renal irritation cleared up, the gouty disturbances have been greatly decreased and with this, probably the best general hygienic treatment in her case, the neurasthenia has been greatly improved, the patient now regarding herself as a well woman.

Taken as a whole there are few subjects that go deeper into the philosophy of practice than this of the relative importance of local lesions and general condition in individual neurasthenics, and few the principles of which are less carefully thought out by many of the profession. In spite of occasional failures in my experience, no other branch of gynecological practice is in the gross more satisfactory.

NEPHRITIS WITHOUT ALBUMEN.

BY C. A. HOWLAND, M.D.,
Pathologist to the Union Hospital, Fall River, Mass.

THIS article will endeavor to show that gross and severe lesions of the kidney may exist without albumen being present in the urine, or at least without being discernible by the methods ordinarily used in hospital and office work. It has long been known that such a pathological condition might exist, but its practical import seems to have been recognized by comparatively few. Those who have recognized it have not considered it sufficiently frequent to warrant exhaustive investigation. In medical literature, the absence of albumen in disease of the kidney is a condition that is almost always considered as accompanying chronic interstitial nephritis, and there is an almost universal belief that absence of albumen indicates the absence of nephritis. Acute nephritis without albumen is regarded by many as an anomaly.

Few physicians in private practice go further in their examination of urine than the tests for sugar and albumen, and comparatively few use the microscope intelligently in their examinations. My investigations in this direction lead me to believe that a large number of patients must be wrongly treated, and many fatally neglected, because of the old and general belief that the absence of albumen usually indicates a healthy kidney.

A brief review of the subject as to the views held by the more commonly accepted authorities may be interesting and pertinent. Wood, in "Chemical and Microscopical Diagnosis," states that "traces of albumen are present in every normal urine, but in such small quantities that they escape detection by ordinary clinical test." In relation to chronic diffuse nephritis the same author says: "Albumen may be absent in a well-marked case, and only a few hyaline casts be found to suggest the possibility of a renal lesion, and this condition may exist when the patient is close to an attack of uremia." Musser, in his "Medical Diagnosis," says: "Tube casts usually indicate acute or chronic nephritis, but they are sometimes found in cases of renal calculi, and in icterus, usually without albumen." In no one of my cases were calculi suspected or was icterus present. The same author, under "Chronic Productive Diffuse Nephritis with Exudation," writes: "The albumen is small in amount or may be absent. Examinations extending over a considerable period of time may disclose its presence." Osler, in his "Practice of Medicine," says, in relation to insurance companies: "Naturally, companies lay great stress upon the presence or absence of albumen, but in the most serious and fatal malady with which they have to deal [chronic interstitial nephritis], the albumen is often absent, or transient, even when the disease is well developed." Under the subject of "amyloid disease," he states: "The albumen is usually abundant, but it may be scanty, in rare instances being absent." Ogden, in "Clinical Examination of Urine," says: "The grave condition [chronic interstitial nephritis] may exist with only the slightest possible trace of albumen in the urine." Professor Bradford, in "Allbutt and Rolleston's System of Medicine," Vol. IV, gives the following under "Granular Kidney": "Granular kidney cannot be excluded in any given instance merely on the ground that albumen is absent on a single occasion. Further, in exceptional instances, albumen may be absent from the urine for a considerable period, and cases

have been recorded from time to time in which granular kidney in an advanced stage has been present and in which death has resulted from uremia, and yet the examination of the urine has failed to reveal the presence of albumen." Holt, in his book entitled, "Infancy and Childhood," discussing acute diffuse nephritis, states: "Albumen was frequently absent early in the attack, but was invariably present at a late period. Casts were found in all cases that were examined microscopically." Under "Chronic Nephritis of the Interstitial Type," he writes: "Albumen is often absent, and, when found, the quantity is small." Sahli states: "The more the disease approaches the type of a true contracted kidney, despite the severity of the disease, the smaller is the amount of albumen excreted, and in an extremely chronic case it may even disappear temporarily. The same variability and temporary disappearance may characterize amyloid disease." All of the above authors, with one exception, admit that chronic interstitial nephritis may exist without albumen; and, with one exception, they do not admit that acute nephritis may be present without albumen. They all fail to impress the reader with the absolute necessity of a microscopical examination of all urine.

From April 1 to December, 1909, I examined 550 specimens of urine in the laboratory of the Union Hospital. All urine was centrifuged from three to six minutes in an electric centrifuge giving from 1,000 to 1,800 revolutions to the minute. The sediment was removed by a thoroughly clean small pipette, the finger being held over the end and the point lowered until just over the sediment. The finger was then removed from the outer end sufficiently to allow only a small amount of the sediment to be admitted into the pipette, which was then held there by replacing the finger on the outer end. The sediment was placed on a glass slide and spread out over at least one square inch of surface, the slide being then placed under the microscope and held in position on a moving stage. The sediment was then examined under low power with closed diaphragm, and by means of the moving stage a systematic search of the whole field made. Heller's nitric acid test was used in all cases, with filtered urine, and the result tested before a dark background. As a rule only morning specimens were used. The average amount was from 6 to 8 oz., and the specimens were not over twelve hours old. In many of the cases recorded numerous examinations were made and several methods employed. Cases in the acute stages which showed casts had their urine examined every few days, and in chronic conditions once or twice a week.

The conclusions that most physicians draw from their examination of urine for albumen are based on the test of a few ounces of what is usually a morning specimen, and not from a part of a twenty-four-hour specimen. The majority use only one test, in many cases probably Heller's nitric acid layer test. This would be sufficient if a careful microscopical examination were also made, as my cases show that the presence of nephritis can be determined when the ordinary clinical tests are carefully carried out, even though only a single specimen be examined.

The accompanying table gives the history of the 21 cases which illustrate the presence of ne-

Case No.	Sex	Age.	Date of First Examination.	Date of Last.	No. Ex.	Diagnosis.	Result.	Final Diagnosis or Cause of Death.	Name.	Service.
No. 1	F.	48	March 24, 1909	March 26, 1909	2	Evulsion of scalp.	Death.	Uremia.	Mrs. C.	Dr. S.
No. 2	F.	37	Aug. 9, 1909	Aug. 31, 1909	13	Typhoid suspected.	Recovery.	Acute nephritis.	Mrs. L.	Dr. J.
No. 3	M.	49	Aug. 28, 1909	Dec. 4, 1909	20	Brain tumor.	Death.	Brain tumor.	Mr. S.	Dr. H.
No. 4	M.	28	Sept. 22, 1909	Sept. 23, 1909	2	Appendicitis.	Recovery.	Appendicitis.	Mr. A.	Dr. W.

No. 8	F.	24	Sept. 20, 1909	Oct. 3, 1909	5	Not made.	Improved.	Nephritis.	Miss T.	Dr. L.
No. 9	M.	50	Oct. 5, 1909	Oct. 5, 1909	1	Progressive gangrene of foot.	Discharged.		Mr. R.	Dr. W.
No. 10	F.	40	Oct. 10, 1909	Oct. 10, 1909	1	Hemorrhoids.	Discharged.		Mrs. M.	Dr. W.
No. 11	M.	37	Oct. 15, 1909	Oct. 15, 1909	1	Not made.	Recovery.	Nephritis.		Dr. L.
No. 12	F.	38	Oct. 16, 1909	Oct. 16, 1909	1	Hemorrhoids.	Discharged.		Miss K.	Dr. D.
No. 13	M.	19	Oct. 20, 1909	Oct. 28, 1909	3	Typhoid.			Mr. H.	Dr. D.
No. 14	F.	36	Oct. 20, 1909	Oct. 31, 1909	6				Mrs. H.	Dr. S.
No. 15	M.	3	Oct. 21, 1909	Nov. 20, 1909	8	Nephritis.	Recovery.	Nephritis.	Mr. B.	Dr. H.
No. 16	F.	38	Oct. 22, 1909	Nov. 8, 1909	8		Discharged.		Mrs. A.	Dr. B.
No. 17	M.	20	Nov. 5, 1909	Nov. 7, 1909	2	Appendicitis.	Discharged.	Appendicitis.	Mrs. P.	Dr. S.
No. 18	F.	17	Nov. 6, 1909	Nov. 7, 1909	2	Peritonitis.	Death.	Uremia.	Miss C.	Dr. S.
No. 19	F.	16	Nov. 11, 1909	Nov. 11, 1909	1	Enlarged glands.	Good.		Miss D.	Dr. D.
No. 20	M.	40	Dec. 12, 1909	Dec. 14, 1909	2	Neurasthenia.	Good.		Mr. W.	Dr. J.
No. 21	M.	45	Dec. 14, 1909	Dec. 18, 1909	2	Sprain.	Good.		Mr. F.	Dr. J.

phritis without the presence of albumen. All cases which showed granular in addition to hyaline casts are included, but not those cases which showed one or two hyaline casts only.

Cases 9, 10, 11 and 12 had only one examination made. After analysis of the urine in Case 11, the patient was treated for congestion of the kidney and made a rapid recovery.

Cases 4, 5, 6, 7 and 17 first showed the presence of casts after the administration of an anesthetic, and there were no serious symptoms that could be attributed to the kidneys. They are important solely in their relation to the effects of an anesthetic on the renal tract.

Nos. 6 and 19 were cases of carcinoma of the stomach, and might suggest a faint possibility of some relation existing between the two conditions.

It is well to note that casts without albumen were found in a large proportion of those cases which were suffering from conditions such as appendicitis, typhoid fever, peritonitis, gangrene and evulsion of the scalp. In these cases the toxins incident to these troubles doubtless had a pathological effect on the kidneys without producing albumen.

CASE 1. Mrs. C., forty-three years of age, admitted to the Union Hospital Jan. 6, 1909, with evulsion of the scalp, the laceration extending down to the fifth cervical vertebra, with involvement of the temporal muscle. The urine was not examined at this time. She did well while in the hospital and was transferred to the out-patient department March 1. She re-entered the hospital March 22. Examination of the urine at this time disclosed no albumen, but an enormous number of granular casts and some few hyaline casts. Death occurred from uremia March 31.

CASE 2. Mrs. L., age thirty-nine, housewife, white, married, no children, previous history good, with the exception of indigestion five years before. Admitted to Union Hospital Aug. 9, with a temperature of 102, pulse 132, respiration 32, typhoid fever being suspected. She had been ill for two weeks before entering, the diagnosis being in question. During this time she had frequent headaches and no appetite. The tongue was dry, there was bad taste in mouth, difficult breathing, nausea and constipation. Respiratory apparatus and circulatory apparatus were normal. Urine examination: Odor normal, cloudy, specific gravity 1,030, albumen absent, sugar absent, indican excessive, bile pigments present, no blood; organized sediment — large number of granular casts, both fine and coarse, with many hyaline casts and epithelial cells; unorganized sediment — amorphous urates. Examination of the nervous system negative, diazo-reaction negative, Widal negative. Blood: Absolute leucocyte count, 11,000; differential count of 200 gave small mononuclear 18%, large mononuclear 0%, neutrophiles 80%, eosinophiles 0%, basophiles 2%. Examinations of the urine were continued from Aug. 10 to Aug. 31; it gradually became free from casts, and on the final examination was in all respects normal. Patient was discharged well.

CASE 15. Master B., age three, white, previous history good, family history fair. Previously had an attack of ileocolitis due to bacillus coli communis infection, from which recovery had apparently taken place. Two weeks later the physician was called because the mother noticed swelling of the eyes, feet and abdomen, with pallor. Examination showed the heart to be normal, temperature 101.1, pulse 116, abdomen somewhat distended by gas and containing a little fluid, and edema about the eyes. Examination of the urine showed it to be free from albumen, though numerous hyaline casts and a few large waxy granular casts were present. The patient improved under treatment and at present is doing fairly well.

CASE 18. Miss C., age seventeen, white, unmarried, previous health good, no occupation. Family history: A sister had uremia and convulsions. Was admitted to the Union Hospital Nov. 5, with acute perforating appendicitis. Temperature, pulse and respiration were typical of peritonitis. Respiratory and circulatory apparatus were normal. Neither the urine nor blood was examined before the operation because of the emergency character of the operation. The abdomen was found to contain pus. The patient was much better the following morning, at which time an examination of the urine showed no albumen, but numerous hyaline casts and a considerable number of fine granular casts. Six hours later she became worse, and a catheterized specimen of the urine showed blood casts and a very large number of fine and coarse granular casts. Death occurred four hours later with all the symptoms of uremic poisoning.

The four cases just given are not to be diagnosed as cases of chronic interstitial nephritis, but are cases of acute destructive processes of the kidney. They show conclusively that albumen may be absent in acute nephritis and that the condition cannot be diagnosed without microscopical examination. Case 2 must be regarded as an instance of acute nephritis without other accompanying diseases. There was an initial high temperature of 103.5, gradually going down to normal, then a secondary rise to 102, reaching normal about the fourth day, with a pulse-rate and respiration somewhat corresponding, the pulse ranging between 120 and 130 during the active stage, falling to about 95; the respiration ranging from 25 to 30 when the temperature was high, being about 20 at the time of discharge.

In the routine examination of 550 specimens, nephritis without albumen was found twenty-one times, or 3.8%. Further examinations from reliable sources, using a thorough technic, will probably give large percentages. This large proportion of unsuspected kidney lesions is probably due to the fact that it is the well-nigh universal custom in both hospitals and by physicians in private practice to examine microscopically only those specimens of urine that show the presence of albumen. It is also the case that many specimens examined microscopically are not previously centrifuged. A part of the onus of such incomplete and unsatisfactory examinations may properly be laid to a certain extent upon the great life insurance companies, who, unless a policy be for a large amount, do not require a microscopical examination of the urine. The very fact that they do require it in policies for large amounts shows that they are cognizant of the possibility of the existence of such conditions as I have been describing. Such thorough examination should be required as a routine measure. All of these 21 cases (with the exception of No. 5, in which sugar was found), so far as the urine was concerned, would have

been acceptable to insurance companies without microscopical examination. It is impossible to say whether these cases would have shown casts without albumen had their urine been examined before the illness which necessitated the present examinations. Many would doubtless have done so, especially those of the chronic interstitial type.

CONCLUSIONS.

No examination of the urine can be called thorough unless a microscopical examination is made. This cannot be satisfactorily done unless the urine is centrifuged in a good centrifuge. No physician can be sure that his patient is free from a kidney lesion without such an examination. Acute nephritis may exist without the presence of albumen, and death may occur with all the symptoms of uremia. Careful pathological study of kidney tissue when during life acute nephritis without albumen has been diagnosed may reveal a distinct type of hitherto unrecognized nephritis. The fact that nephritis may accompany other severe diseased conditions does not lessen its importance. The knowledge of its existence will to a great degree influence the treatment and prognosis.

DRUGS IN PRACTICE.*

BY M. VEJUX TYRODE, M.D., BOSTON.

It is with much pleasure that I have accepted your kind invitation to speak to-night on drugs in practice, because although that branch of therapeutics may in the past have occupied the whole field, to the detriment of other divisions, yet during the last twenty or thirty years, or more, therapeutics by drugs from a scientific point of view has received very inadequate attention from many medical schools and from practitioners in general.

Before beginning the subject, I would beg you to allow me to give my definition of a drug, as it seems that there is often great misconception concerning this point.

A drug is any substance other than a foodstuff or a purely mechanical agent which is capable of producing changes in a living organism while in a normal or pathological state. This naturally includes all substances of animal, vegetable or mineral origin which are capable of influencing the metabolism of the whole or of some parts of living beings. Thus vaccines of hydrophobia and smallpox or the antitoxins of diphtheria, cerebrospinal meningitis, streptococcus infection, etc., are true drugs, just as much as iron, cinchona, thyroid extract, bile or pepsin, for they all produce certain definite actions in living organisms.

In spite of the efforts of cranks on psychotherapy, dietetics and physical therapeutics to abolish the use of drugs or belittle their advantage in the treatment of disease, these therapeutic agents have persisted and are still flourishing after the late passing period of therapeutic nihilism. This is very encouraging, because unquestionably great good is being done every day by the proper use of drugs. Few well-trained modern physicians would think of treating malaria without quinine, or diphtheria without the antitoxin. In the same way a doctor called to see a case of extreme cardiac uncompensation would almost be guilty of criminal negligence if he did not attempt to strengthen the force of the heart muscles with a suitable cardiac tonic. No physician who has carefully studied the action of iron preparations in cases of non-pernicious anemias would question the value of these. Likewise the wonderful effect upon myxedema of thyroid extract has struck every one who has ever tried that drug in such cases.

It is unnecessary to defend the rights and accomplishments of drugs in modern therapeutics because the results obtained speak glowingly for themselves. With the great activity which is going on all over the world on the question of specific therapy, and the masterly work done by the French, English and Ehrlich school on the actions of arsenical compounds, aniline dyes, etc., on certain infectious conditions, such as sleeping sickness and other trypanosomatous diseases, there is a promise that drugs even other than vaccines and antitoxins will find a more and more important place in therapeutics. Yet, I do not say this to belittle the other branches of therapy, as dietetics, psychotherapy and physical therapeutics, as I use them all freely in practice myself.

Since a great deal of my special work is on diseases of the stomach and intestines, I find scientific dieting particularly valuable. In neurotic conditions of the gastro-intestinal tract, suggestion is sometimes a most valuable adjuvant. Likewise I feel that I cannot neglect prescribing physical methods, as proper exercise, baths and, in suitable cases, massage and electricity. The greatest of all physical methods of treatment, surgery, must be judiciously advised in its proper indication. Thus it can be replaced by no other measures in certain cases of gastric dilatation with pyloric obstruction, gallstones, chronic appendicitis and scores of other abdominal conditions that can be influenced neither by diet, suggestive treatment, drugs nor by the other mechanical means except surgery.

Yet, in spite of the frequent use which I make of other remedial agents, I would be very unwilling to be deprived of the use of drugs even in my favorite branch of gastro-intestinal diseases, where many enthusiastic dietitians claim that drugs are of but little value.

To give you just a slight idea of some therapeutic effects obtained in my practice, I will mention results reached by a few drugs. In a case of ulcerative colitis to which I was called in consultation and found by sigmoidal examination a number of raw angry-looking ulcers and patient having from twenty to forty stools a day in spite of a very simple cornstarch diet which the doctor had been giving for the past three or four weeks, I ordered a suspension of bismuth and acacia to be injected high into the colon and retained.

* Read before the Cambridge Medical Improvement Society, April 25, 1910.

Within forty eight hours the patient had but three stools a day. The latter gradually acquired a normal consistency and the patient made an uneventful recovery. Another, a case of extreme hyperacidity, 0.35% Hcl, with duodenal ulcer, came to me from New York after having had three weeks of almost continual spasmodic pain and terrible burning in the stomach, expressed by the patient, "everything I take turns to acid." As is my custom in these cases, I gave him repeated doses of the heavy oxide of magnesia in watery suspension, and in twenty-four hours all pain and spasm had disappeared, and with a careful hyperacidity diet he went six months without feeling a symptom, until, during a trip in Germany, he drank beer rather freely and ate sauerkraut and Bismarck herrings and had another attack which was stopped the same way in a few days. Six months later, as he had a much more persistent attack, due to some other indiscretions, I advised operation, which was completely successful. A lady was referred to me by another physician to decide on the question of cancer of the stomach. She was about fifty-five years of age, had lost about 25 lb. in weight during the last six or eight months and there was no hydrochloric acid after an Ewald test breakfast. I gave her dilute hydrochloric acid in increasing doses, the burning and vomiting stopped, she gained in the course of a week 13 lb. and continued thereafter to improve. She was not suffering from cancer, but from an atrophic catarrh of the mucous membrane of the stomach. A young society girl who had been crossed in love by her family had developed complete anorexia, with terrible pains in the stomach, even with the slightest amount of food; also palpitations of the heart, headaches, backaches, fretfulness and sleeplessness. Considering the condition as one of nervous fatigue with irritable symptoms, and the stomach being simply an evidence of the peripheral manifestations due to an over-secretion of hydrochloric acid, she was placed on the treatment by bromides, with the result that in the course of a few days she slept perfectly well, the gastric distress was rapidly passing away and in the course of a few weeks she gained 14 or 15 lb. A case of a young professional woman who had had the most obstinate constipation for a number of years, with pain and pressure in the lower bowel, and who showed the presence of chronic irritation of the colon and sigmoid due to both the retained feces and the abuse of rough diet generally employed in constipation. She was placed upon smooth diet and given liquid petroleum for its soothing effect upon the intestinal mucosa and also to prevent too great inspissation of the stool. Now, nearly a year after the beginning of the treatment, she has no constipation even without the use of the petroleum.

Nowadays, gentlemen, the question is not "Drug or Drugless Therapy?" as that has been solved for the present; but it is how to use suitable drugs properly. The injudicious and indiscriminately large amount of drugs used in the early part of the last century favored the development of therapeutic nihilism.

It was that indifference to all treatment when diagnosis was considered the only worthy object and end result which gave the opportunity for the development of the various quackeries of all characters included in the classes of psychotherapy, physical, dietetic and medicinal therapeutics. Thus, special religious sects sprang up offering suggestive treatment as the cure for all ailments; also certain "pathies" offered mechanical treatment in the form of massage, with such exaggerated claims that organic conditions of the stomach, as ulcer or cancer, and also diabetes, could be cured by rubbing the spine. Other mechanical "therapists" have had the audacity to write to sick individuals or to send drummers representing them stating that they could cure almost any condition if the patient would follow a certain system of exercise, which they would direct by mail, according to the symptoms, without even seeing the patient.

Among the most colossal of therapeutic quackeries have been those falling in the medicinal class. At first such simple combinations as the various sarsaparillas, spring tonics and purgative or little liver pills advertised to the public constituted the beginning of the present-day patent medicine "profession." It was gradually found out by the sharp and crafty business men that unsuspecting physicians could be made an excellent medium for advertisement, as they could be easily persuaded to prescribe those "ethical" preparations only advertised to the profession. Yet these "ethical" preparations were frequently dispensed in the original package, accompanied by voluminous explanatory literature on the symptoms which this medicine would relieve. The doctor fell in admirably with the scheme of the patent medicine manufacturer for various reasons. One is that in many schools, and this applies here in the East, very inadequate instruction in pharmacology and therapeutics is given to the medical students, so that many physicians find it very difficult to write prescriptions. Another is that it is an economy of time to write one name constituting a ready-made prescription. Yet another is that the doctor has been assured by the agents that it is a perfectly ethical thing to do because the famous Doctor So and So is prescribing this medicine. Still another reason is because the doctor, frequently victim of autosuggestion like any other human being, and insufficiently trained to exact observation, thinks that he is getting good results from a certain preparation, whereas he really has not subjected it to an absolutely critical test. Patent preparations, as, for example, digestive mixtures, may act through suggestion, or the improvement may be the result of changes of diet or more air, of exercise or diminution of mental strain. A great argument against specific virtues attached to these digestive tablets, mixtures or essences is that each doctor has one picked out for which he claims absolute results, but in a group of ten physicians taken at random no two swear

by the same patent preparation, and one or two out of these ten get their results, which they claim to be just as marvelous, by official drugs. One objection brought by some physicians against National Formulary preparations instead of patent mixtures representing the same is that the druggist will not make as elegant a compound from the National Formulary formula. The answer is that although a few formulas are not perfect in the National Formulary, yet many of the cases are due to inefficient pharmacists or the use of poor material. This is to my mind a still more forceful argument for doctors not using any ready made up mixtures at all, whether patent or National Formulary, but to prescribe his own, and with a reliable druggist he will meet with no trouble.

Fortunately, the American Medical Association has taken up the subject of patent medicine for investigation. This body has established a Council on Pharmacy and Chemistry to investigate the patent and patented medicines on the market and to discriminate which are out-and-out fraud and which are correctly advertised and might be possessed of some therapeutic value. This work is admirable and it would pay any of you gentlemen who have not done so already to read the publications of that Association, such as the "Physician's Manual of the U. S. Pharmacopea and National Formulary," the "New and Non-Official Remedies the Propaganda for Reform in Proprietary Medicines," the "Great American Fraud," etc. In the "New and Non-Official Remedies" are to be found the new proprietary drugs examined by the Council and passed upon as being truthfully advertised, although this does not imply endorsement by the Association. If a physician wishes to use some of these newer drugs he must pick them out himself according to his knowledge of pharmacology and chemistry.

There is no doubt that this flood of new drugs and combinations has its chief value in increasing the income of the manufacturers rather than advancing the art of therapeutics, for it is not so much a large number of a certain class of medicinal agents which we need, but rather a better understanding of the already known ones. It is true that we must place great hopes in the development of synthetic pharmacology, i. e., the building up of new compounds having certain desirable actions but not possessing certain undesirable ones at the same time. Yet for a few successful synthetics we have thousands of unsuccessful ones on the market which are pushed commercially far beyond their medicinal value and exploited purely for personal gain. For instance, of the hundreds of newer coal tars as antipyretics and analgesics none have really surpassed some of the older compounds. The newer artificial morphine derivatives have not proved themselves as valuable as morphine and codeine. In my own practice, I have tried the new bromide substitutes but have not found them equal to potassium bromide. Chloral still remains the most powerful hypnotic of the fatty acid series and is far superior in activity to any of its substitutes, and frequently not much more dangerous.

Although some good has come from the synthesis of new compounds, and still more good will come in the future occasionally from purely scientific laboratories and at other times from the laboratories of manufacturing chemists, yet it is much safer for the average physician who is not a trained pharmacologist to use drugs the actions of which he is sure of rather than to experiment upon his patients with uncertainties. He would be wiser to wait until newer drugs have been throughly experimented upon by reliable men in unbiased laboratories and hospitals, which procedure may take several years.

What I have said up to the present applies only to new pure chemical compounds, but now let us consider the various mixtures or ready put up prescriptions, as So-and-So's tonic, or syrup of hypophosphite, or malt extract or purgative pills. These can be easily disposed of with but a few words: that a physician who pretends to treat patients should know how to mix drugs in a prescription himself without the suggestions of a patent medicine house, and, furthermore, if he desires any ready made mixtures, which I rarely use myself, he can find all sorts in the United States Pharmacopea and National Formulary.

In these books you will find over a dozen laxative pills which can be easily put up by any reliable druggist and which are equal to any of those on the market under trade names; also syrups of hypophosphites, of hydriodic acid, glycerophosphates, etc.; tonics of all kinds, organic and inorganic salts of iron, innumerable elixirs which act as excellent vehicles and which obviate the use of patented essences of pepsin chiefly employed as a vehicle, since the pepsin in them is rendered inert by alcohol and, in fact, is present in such small quantities that quarts would be necessary to digest a helping of beefsteak. Much better results at lower cost will be obtained by using home-made beef juice, scraped beef, etc., instead of the patented beef-preparations; likewise arrow-root, cornstarch, blanc-mange, barley-water, tapioca and rice will advantageously fill the place of the patented cereals, as the malted milks and infant foods. Instead of the patented fats, as various emulsions of cod-liver oil, and some particular frauds claiming to contain the active principles of cod-liver oil without the disagreable fat, far better results may be reached by the employment of cream, milk and olive oil. If one wishes to use alcoholic preparations, the ordinary good brands of wine, beer, ales and spirits will not only equal but excel any patent wines or malt extracts. The farcical use of uric acid solvents, as patented lithia waters and certain piperazin compounds, can be advantageously substituted by the use of large amounts of ordinary water with simple alkaline salts, as potassium citrate and sodium bicarbonate. In the United States Pharmacopea we have an excellent urinary antiseptic under the name of hexamethylenamine—an unfortunately long name,

but which occurs on the market patented under about ten different names, as urotropine, cystogen, uriform, aminoform, uritone, formin, etc. These various preparations having no advantage over the Pharmacopeal compound, there is certainly no reason for prescribing those much more expensive names of identical chemical composition.

The question may be asked here, What is the objection to using a patent compound or mixture if it acts as well as something in the Pharmacopea? In the first place, a proprietary preparation has no standard except that which the firm is willing to give it and is, therefore, unreliable, being frequently changeable in composition from time to time, or even at the same time from state to state. Another reason is that as physicians we are morally bound to protect our patients' interest and, therefore, should not unnecessarily turn them over into mercenary hands.

Another question arises whether we are justified in specifying in our prescription for well-known chemical compounds the manufacture of certain firms. We have as physicians just as much right to do this as chemists who frequently specify. When we have evidence that a certain firm makes a purer and more active product, we are perfectly justified in specifying even if it is more expensive for the patient. This, however, we should not do unless we have definite evidence of superiority and reliability for making the preference.

I have had considerable concern in the coming revision of the Pharmacopea, being a delegate from The Massachusetts Medical Society, and have observed far greater interest than has ever been evinced before by the medical profession. The former pharmacopeas have not been all that they should be as far as being very practical works for physicians, because they were gotten up almost exclusively by the pharmaceutical profession, from a pharmaceutical viewpoint, as the medical men had relinquished practically all interest in it. The pharmaceutical men had been unjustly accused of having robbed the Pharmacopea from the medical profession. This was an exceedingly unjust accusation. On general occasions when I was invited to address the New England branch of the American Pharmaceutical Association I found the most earnest and eager desire of the pharmacists to interest the medical men in the Pharmacopea in order to make it a very practical book in medicine. From what is being done for the purification and reorganization of the new Pharmacopea, I dare say that it will probably be a masterpiece of its kind and a most practical book for physicians, whence they may draw their safest and most active materia medica. Until the new Pharmacopea and National Formulary appear, I cannot recommend too strongly the Physician's Manual of the Pharmacopea and the National Formulary, published by the American Medical Association, and hope that those of you who have not one already will procure this valuable little book.

THE SPUTUM OF TYPHOID FEVER PATIENTS AS A POSSIBLE SOURCE OF INFECTION.*

BY ELMER S. TENNEY, B.L., M.D., U. S. ARMY, FORT STRONG, MASS.
(From the Department of Preventive Medicine and Hygiene, Harvard Medical School.)

AT the suggestion of Dr. Rosenau, and with his kind advice and assistance, I have been able to carry out the following study of the saliva and sputum of 53 cases of typhoid fever.

Thanks are due to Dr. MacCollom, superintendent of the Boston City Hospital; to Dr. Washburn, superintendent of the Massachusetts General Hospital, and to Dr. Lucas, of the Children's Hospital, for kindly placing at my disposal the cases of typhoid occurring at these hospitals during the past winter.

So far as I am aware from a careful examination of the available literature, very little of a definite nature has been published in relation to the infectiousness of the saliva and sputum of typhoid fever patients. In reviewing the literature the impression one gets is that the bacillus typhosus is not frequently to be found in the mouth; that it may be, but usually is not, the cause of pneumonia complicating typhoid fever; and that while thus rarely to be found in the mouth, still, because it may be found there, the saliva and sputum should be treated as a possible source of infection.

No writer except Richardson whom I have consulted makes any definite statement that he has himself done any experimental work upon the subject or quotes the writings of any one who has. To give an idea of what seems to be the opinions most commonly held upon the subject, I will refer briefly to the expressions of a few writers.

Osler and also Field seem to think that the typhoid bacillus is to be found in the mouth more frequently than the majority of writers. In the latest revised edition (1909) of his "Practice of Medicine," Osler says, "They are reported to have been cultivated from the sweat, and they undoubtedly occur with considerable frequency in the sputum (Richardson, Raw and others)"; he further says, "They are also present in the esophagus and on the tongue and tonsils."

The work of Richardson referred to by Osler was published in the BOSTON MEDICAL AND SURGICAL JOURNAL, in 1903, and is as follows, "As to the presence of the typhoid bacillus in the sputum, I was able, in 1897 [*Journal of the Boston Society of Medical Sciences*, Nov. 16, 1897], to isolate this organism on three successive days from the sputum of a case of typhoid fever complicated with pneumonia. In 15 cases with no pulmonary complications the results were negative. Since 1897 the subject has been investigated by a few observers only. Their results show that the typhoid bacillus may be present in the sputum during typhoid fever, especially if there be a coincident bronchitis or pneumonia. The typhoid bacilli are almost invariably associated with other organisms, such as the pneumococcus or the influenza bacillus, and are to be regarded rather as secondary invaders than as the primary cause of

* Read by title at the annual meeting of the American Society of Tropical Medicine at St. Louis, June 11, 1910.

the complication. The sputum in these cases is generally hemorrhagic and may contain large numbers of bacilli for considerable lengths of time. Seven weeks is the longest period of persistence recorded. The subject needs much further study, but enough is known to show that in the typhoid sputum we have still another excretion which must be carefully disinfected."

Under the heading of the "Distribution of the Typhoid Bacillus in the Body," Field says, "The finding of the typhoid bacillus by Besson in the tonsils of 6 out of 10 cases investigated warrants the belief that they also exist in the mouth." Jordan, in his "Textbook on Bacteriology," says, "Typhoid bacilli have been found occasionally in the sputum, although the majority of cases of pneumonia that occur during the course of typhoid fever are apparently caused by the pneumococcus. There is hence a possibility that typhoid fever may be spread by sputum infection, but it seems rather remote." Whipple states that "in some cases bacilli are found in the mouth and throat; consequently the saliva may contain them. This condition may be infrequent, but it is always liable to occur. There is practically no danger to be feared from the quietly exhaled breath, as bacteria do not readily leave a moist surface; but coughing or sneezing may cause the expulsion of the bacilli into the atmosphere, with consequent danger to persons in the room who may inhale them." Tooth, writing of his observations in the South African War, in "A Civilian War Hospital," 1901, makes the following statement: "In a tentful of men, apparently equally ill, one may almost pick out the enteric cases by the masses of flies that they attract. . . . The moment an enteric patient puts out his tongue, one or more flies settle on it." It might be inferred from this remark of Tooth's that he thought flies could thus become infected. Rosenau, in his work on "Disinfection and Disinfectants," says that "the bacillus of typhoid fever is eliminated from the body in the stools, the urine and sometimes in the sputum." In 1897 J. C. Wilson, writing in the "American System of Practical Medicine," was of the opinion that "by far the largest proportion of the bacilli are without doubt destroyed within the body. The remainder find their way out in the stools, to a slight extent in the urine, very rarely in the vomited or expectorated matters, or the perspiration. They are not eliminated by the expired air. . . . . Croupous pneumonia is, however, in some instances apparently due, not to infection by the diplococcus of pneumonia, but to infection by the bacillus of Eberth. Under these circumstances it usually occurs early in the course of the attack, and has been attributed to localization of the specific process. The difference between the two forms, however, is rather a bacteriological than an anatomical one." In a case of mine in the Jefferson Hospital, Coplin found Eberth's bacillus in the pulmonary exudate. H. W. Hill, of the Minnesota State Board of Health laboratories, says, "All our forms of outbreaks are merely the result of the following, by typhoid infected feces chiefly, but also by typhoid urine and saliva. . . ." To quote again from Jordan's "Bacteriology," "The actual evidence in favor of the invasion of the body through the tonsils and gastric mucosa is by some investigators thought to be quite as strong as the evidence of intestinal penetration." Kolle and Hetsch, in "Die Experimentelle Bakteriologie und die Infectionskrankheitens," say that the typhoid bacillus is rarely to be found in the mouth or sputum. On Dec. 20, 1909, at a meeting of the Medical Association of the Greater City of New York, as a part of a "Symposium on the Throat Symptoms of General Diseases," Dr. Coffin discussed the laryngeal complications of typhoid fever, calling attention to the fact that the larynx is much more frequently involved in some localities than in others, and most often in the severer epidemics. He quoted a paper by Drs. Jackson and Day, of Pittsburg, written some years ago, in which they reported that "of 360 cases that were carefully watched throughout the course of the disease, 227 showed lesions in the larynx." Of these cases, he said that some showed simply a subacute laryngitis, others a laryngitis with an ulceration of the mucous membrane, while in the more severe cases the cartilages and pericartilaginous tissues were involved.

Following Dr. Coffin, Dr. Nathan B. Van Etten said that "the uvula, tonsils and pharynx were often ulcerated, and, in cultures from these ulcers, typhoid bacilli had often been obtained. The frequent finding of the bacilli in the sputum indicated the necessity of the destruction of all mouth secretions as sources of infection." (The quotations above are from the "Society Reports" in the *Medical Record* of March 12, 1910, page 465.) That every victim of typhoid fever must receive his infection through the mouth is an admitted fact; ordinarily this occurs through the introduction of food or drink, the greater part of which passes directly to the stomach, but it is not unreasonable to suppose that small contaminated particles may find lodgment upon the teeth and gums, where, if conditions be right, they should readily multiply. The saliva usually has a weak alkaline reaction which makes it, so far as that point is concerned, suitable for the growth of the typhoid bacillus, and as the result of actual trial I have found that it will readily multiply in it. If, then, the infecting bacilli must first pass through the mouth to reach the blood stream, and if the saliva in the mouth is a suitable medium for its growth, why should the bacillus not be found in the saliva in sufficient numbers to be demonstrated with the proper technic and, of course, be a possible source of danger to others? It was with the idea of determining, if possible, the above question that this work was begun. It was further hoped that, in addition, something might be learned as to its frequency at the different stages of the disease. The work was begun in the autumn, but not completed until the following spring, owing to the scarcity of material. As the list of the tabulated cases which follows will show, material was obtained from cases as early as the

fourth day of illness and as late as the seventieth; specimens were secured from seven cases several days before a positive Widal reaction could be obtained.

The material studied consisted of the expectoration, collected in the ordinary sputum collecting bottles in use by the Boston Board of Health; and, in addition, material was collected on ordinary diphtheria swabs from the tonsils, the surface of the tongue, the gums and any carious teeth that might happen to be present.

These specimens were invariably brought to the laboratory within one hour of the time of collection, diluted with about four parts of normal salt solution and then thoroughly shaken and mixed; it was allowed to stand while the culture medium was being prepared and again shaken before the plates were inoculated.

The medium used was Endo's fuchsin agar, made after the modification recommended by the Hygienic Laboratory at Washington (see Hygienic Laboratory Bulletin, No. 52, October, 1909, Report No. 3, on "The Origin and Prevalence of Typhoid Fever in the District of Columbia," 1908, by M. J. Rosenau, L. L. Lumsden and Joseph H. Kastle), which are as follows: "Make 4% neutral agar as follows: Take 1 liter distilled water, add 5 gm. sodium chloride, 10 gm. Liebig's extract meat, 10 gm. peptone. Dissolve by heating, allow to cool, and place on surface 40 gm. powdered agar.

"When this has settled, place in Arnold sterilizer, covering beaker with paper, and cook for three hours.

"Filter through cotton on a perforated funnel (*Büchnerfilter*) by the aid of a vacuum, or allow to settle while slowly cooling and discard the bottom turbid portion.

"Neutralize to litmus paper with Na_2CO_3 solution. Add 10 ccm. sterile 10% Na_2CO_3 solution.

"It is convenient at this point to put up the medium in 100, 200 and 400 ccm. quantities in flasks, the flasks being large enough to provide room for the other ingredients.

"These can be stored until needed for use; the agar is melted and the other ingredients added in the proper proportion.

"Add 5 ccm. alcoholic fuchsin solution. This is prepared as follows: To 10 gm. fuchsin (not acid fuchsin) add 100 ccm. 96% alcohol, shake, allow to stand twenty hours, and filter the supernatant fluid which is used. It should be filtered each time before using.

"Add 25 ccm. freshly made and sterilized 10% sodium sulphite solution.

"Sterilize for a few minutes in the Arnold and pour plates while the medium is steaming hot.

"The medium after cooling should be nearly colorless to transmitted light and rose or flesh-colored to reflected light.

"The lactose, fuchsin and sodium sulphite solutions must be added to the melted agar just before it is to be used.

"The plates are flown and allowed to stand for twenty minutes (my plates were given one hour) uncovered in the incubator in order to do away with the water of condensation and to obtain a good surface.

"Organisms which split lactose restore the red fuchsin and appear as deep red sharply limited opaque colonies with a greenish surface sheen.

"The typhoid organism produces smaller transparent colonies resembling a small drop of water."

The plates were inoculated with a sterile glass rod which had been bent at a right angle, the short arm being dipped into the thoroughly mixed material in the salt solution and then rubbed firmly and evenly over the surface of the plate and successively over a second and third in order to get the necessary distribution of colonies. The plates were incubated at 37° C. for twenty-four hours, and then subcultures in plain boullion were made from all suspicious-looking colonies. Each tube of plain boullion containing about 4 ccm. was incubated for twenty-four hours, after which a small drop of Parke, Davis & Co. typhoid serum was added, making a dilution of not far from 1 to 400. This serum when tested against a laboratory culture of typhoid which I isolated about one year ago showed marked agglutination in fifteen minutes in dilutions of 1 to 1000, and quite perceptible clumping in less than two hours in dilutions of 1 to 2500. The tubes were examined after one hour and the results recorded, but all were allowed to stand for twenty-four hours and again examined, at which time, if any tube showed what appeared to be a partial agglutination, it was put aside for further study. Whenever material was obtained upon swabs, after the Endo plates had been inoculated, the swabs were used to inoculate lactose boullion fermentation tubes, from which additional Endo plates were made the following day; and all suspicious colonies on these plates were treated in the same manner as above, as it was thought that by this enriching process the bacilli might be discovered in cases where they were only present in small numbers. It was found that only a small number of the organisms occurring in the mouth will grow on Endo's medium and that every one of these has a more or less distinctive appearance in colonies to distinguish it from colonies of typhoid or other members of the typhoid group. In nine of these cases there were bronchial symptoms, but in none was there a case of pneumonia; it was not observed that there was any variation in the varieties grown from these and those without such symptoms. No throat complications, such as described by Drs. Coffin and Van Etten, were noticed in any of this series.

The work was controlled in the following manner. A plate inoculated with a laboratory culture of typhoid bacilli was always made as a check on each batch of medium throughout the work; and during the early part, in order to test out the whole technic, ten specimens of saliva and sputum, two of which ("T" and "X") were known to have been inoculated with two loopfuls of an agar typhoid culture and eight of

which were prepared by other persons and about which nothing was known to the writer. The colonies of each of the "unknowns" were so typical that, in every instance, I was able to pick those containing typhoid bacilli before resorting to the serum agglutination test, which I did later to confirm my opinion. Finding that my technic appeared to be satisfactory, I turned these "control cultures" to a new purpose by making Endo plates from those which were positive, at intervals, in order to ascertain if the bacilli would keep alive in the sputum for any considerable length of time. As the chart shows, all were alive at the end of sixty-one days, but "C" and "G" were not alive at the end of eighty-four days, or at least, if typhoid bacilli were still present, they were not demonstrable with the technic employed. Plates from those two specimens showed colonies resembling the ordinary typhoid colonies somewhat, but inclined to be more opaque, and did not agglutinate. In order to find out if saliva and sputum makes a suitable medium for the growth of typhoid bacilli, I made transplants from specimen "X," when it was twenty-one days old, into fresh saliva and sputum (this became "X transplant"), and sixteen days later I transplanted this into still another fresh specimen of the same material, which became "X transplant No. 2." Thirty-eight days later I inoculated another fresh lot of

material from "X transplant No. 2," which thus became "X transplant No. 3." All of these subcultures were plated out on Endo's medium in the same manner as the specimens obtained from typhoid patients, and each gave a positive reaction when tested with the typhoid serum. Usually after the inoculated specimens were three weeks old, the plates showed very little beside typhoid colonies, the other organisms which were present on the plates made from the freshly inoculated saliva and sputum being apparently less resistant. In transplanting from one specimen to another one loopful of the old was added to about 4 ccm. of the material; these were always left in the laboratory at room temperature.

SUMMARY.

In a study of the saliva and sputum of 53 cases of typhoid fever, several of which showed bronchial symptoms, but none pneumonia or any laryngeal complications, the bacillus was not found by means of the technic employed.

Typhoid bacilli will live for at least one hundred and twenty-five days in the saliva and sputum and can be readily transplanted from one specimen of such material to another and kept growing in it at room temperature for a long time.

CONCULSIONS.

The examination of this limited number of cases shows that, in those uncomplicated by pneumonia or by laryngeal inflammation, the typhoid bacillus is not frequently found in the mouth.

In view of the reported finding of the bacillus in cases complicated by pneumonia and by laryngeal inflammation, it would seem that more work, especially upon cases showing these symptoms, should be done along the lines followed in this series.

While the sputum does not frequently contain the typhoid bacillus, it does so occasionally, and on that account it cannot be ignored as a source of infection.

THE NASAL SEPTUM: IMPORTANT POINTS IN ANATOMY AND SUBMUCOUS RESECTION.

BY OLIVER A. LOTHROP, M.D., BOSTON.

THE adult nasal septum is rarely perfectly straight and free from thickened areas and spurs. When the deflection and spurs are of such proportions as to cause nasal obstruction, resection

is indicated. A deviation or deflection is found only in the quadrangular cartilage and perpendicular plate of the ethmoid. The deflection may be a simple or double curve; it may be angular, resulting from a fractured cartilage. The septum

may be complexly distorted. Spurs and ridges may form on one or both sides of the septum. They are found at the line of suture formed by the cartilage and perpendicular plate of the ethmoid above, and the premaxilla and vomer below.

A clear understanding of the anatomy of the premaxilla and the vomer, their relations to one another and to the quadrangular cartilage, is most important. The premaxilla is a small, wedge-shaped bone which completes the anterior part of the hard palate and forms that portion of the alveolar process that supports the four upper incisor teeth. On the floor of the nose it presents a median grooved ridge. The anterior point is called the anterior nasal spine. Posteriorly, the borders of the groove expand into leaf-like processes called the premaxillary wings. The distance from the spine to the posterior extremity of these wings is about three quarters of an inch. The dipping down of the floor of the nose makes the posterior part of this ridge relatively higher than the anterior.

The vomer is a thin, quadrangular-shaped bone forming the inferior and posterior part of the septum. The inferior border articulates loosely with the median ridge formed at the junction of the palatal processes of the superior maxilla and the horizontal processes of the palate bones. The posterior border is free and forms the full height of the septum at the posterior choanæ. The superior border articulates with the body of the sphenoid bone. The anterior border is straight and has a groove like the premaxilla. This groove may extend quite deeply between the lateral leaves of the vomer. The anterior angle articulates with the premaxilla and rests within its groove. The naso-palatine artery and nerve lie in a groove along the side of the vomer parallel to the anterior border, and pass through the anterior palatine canal between the premaxilla and the palatal process of the superior maxilla.

The perpendicular plate of the ethmoid forms the superior and posterior parts of the septum, and the lower portion of its posterior border articulates with the groove on the anterior border of the vomer. This bone is very thin except at its anterior border.

The quadrangular cartilage completes the superior and anterior part of the septum. It articulates firmly with the inferior border of the perpendicular plate of tne ethmoid, and its inferior border rests within the groove of the vomer and premaxilla. This cartilage supports the tip of the nose and the bridge below the nasal bones.

A layer of mucous membrane covers both sides of the septum. This is adherent to the underlying perichondrium and periosteum of the septal bones and cartilage. The deepest layer of perichondrium and periosteum is easily separated from the cartilage and bones. It is only slightly adherent at the sutures, except where the cartilage joins the premaxilla. An examination of a large number of anatomical specimens shows that the deepest layer of perichondrium passes around the inferior border of the cartilage, between it and the premaxilla, joining with that of the other side. A thin, inner layer of periosteum is likewise reflected over the premaxillary wings and the groove of the premaxilla. This layer is fused with that of the perichondrium, and both are very adherent to the bone, but not to the border of the cartilage.

Many theories as to the etiology of deflections and spurs have been offered. It is not the purpose of this paper to enumerate or discuss these. In general it may be said that deflections are the result of unequal growth of the cranial bones. The fault may lie within the septum or in the

parts connected with it. The cartilage and perpendicular plate of the ethmoid are bent or distorted. Spurs and ridges are formed by the dislocation of the inferior border of the cartilage from the groove in the vomer and premaxilla. The border may be thickened, thus increasing the size of the spur. Thickening of the border of the cartilage without dislocation may take place, forming a rounded spur or ridge. The relations of the soft parts to the cartilage and premaxilla, as above described, are not altered by dislocation or thickening. Sometimes a strip of cartilage extends back between the ethmoid and vomer along the suture. In such cases a ridge may extend back to the sphenoid. In extreme cases the vomer may be dislocated from the premaxilla. Unequal eruption of the second dentition may tilt the premaxilla to either side, favoring dislocation of the cartilage to the lower side. Trauma is a less frequent cause of deflection of the cartilage. In these cases the deflection is often angular, well anterior and vertical in direction.

An accurate knowledge of the finer points of anatomy of the septum will greatly simplify the technic of submucous resection. In making the primary incision, the fact that the muco-perichondrium can be split into layers is important. None of these layers separate readily, but the deepest layer of perichondrium may be elevated easily from the cartilage; therefore, the incision should be carried to the cartilage before elevation is attempted. Unfortunately, the cartilage is very thin under the center of the primary incision. With the dissection started in the proper plane of cleavage, and with no angular deformity of the septum, a straight, blunt dissector may be pushed up parallel to the bridge of the nose as far as desired, and then the whole shaft swept downward to the anterior border of the vomer. The cartilage may now be divided opposite the initial line of incision and a similar stroke used to separate the soft parts of the other side.

In cases in which there is an angular deflection and an old fracture of the cartilage, a layer of fibrous tissue is found running in between the fragments. In this type it is unsafe to attempt to force the elevating past this scar tissue because there is danger of perforating the mucous membrane. The cartilage may be denuded as far as the line of fracture, and it will be found that the anterior fragment, when incised above and below, can be separated from the posterior fragment. If the fibers over the anterior edge of the posterior fragment be incised or scraped away with a sharp dissector, a fresh line of a cleavage can be started easily.

The septum is thickened at the junction of the cartilage and ethmoid. The union between the cartilage and bone is very solid and does not dislocate. The line of suture is often irregular and, roughly, is at right angles to the line of vision from the vestibule. The perichondrium is slightly adherent at this line, but does not communicate with the other side. The muco-periosteum elevates more easily from the ethmoid, but is thinner. The plate of bone itself may be so thin that the elevator penetrates accidently to the other side. The line of suture between the cartilage and the ethmoid is approximately opposite and parallel with the lower border of the middle turbinate in many cases. In abnormal thickening the turbinate is forced outward, interfering with the drainage from the anterior ethmoid cells and frontal sinus. This thickened suture should always be resected.

The most difficult portion of the septum resection is along the inferior border of the cartilage which articulates in the groove of the vomer and premaxilla. It is along this suture that the troublesome spurs and ridges are found. The soft parts cannot be elevated below this suture except posterior to the wings of the premaxilla. From here the separating may be continued down on the sides of the vomer provided there is not too sharp or too large a ridge to pass over. The vomer is rather rough and the soft parts do not separate so easily as over the ethmoid. In some cases the cartilage is lodged in an exceptionally deep groove of the vomer. In these instances the elevator is arrested by the lateral projections of the vomer, and a plane of cleavage must be started along this edge of bone and the separation continued downward.

Before attempting to separate the soft parts from the premaxilla and spur connected with it, remove the section of cartilage that has been denuded. The inferior border of the cartilage, whether dislocated or thickened, is then easily enucleated from its bed. The primary incision in the cartilage should first be carried down well into the groove in the premaxilla. The tissue which unites the two layers of soft parts and passes between the cartilage and the premaxilla is now exposed. This should be incised parallel with and close to the border of the premaxillary wing on either side, cutting downward against the bone. The severed tissue should be scraped from the bone over the border of the premaxillary wings, when it will be found that the muco-periosteum separates readily from the sides of the premaxillary ridge and wings down to the floor of the nose. The denuded premaxillary wings and ridge can then be removed easily with bone-cutting forceps.

The primary incision should be made preferably on the side having the sharpest spur. This leaves undisturbed the side which offers the best hope of separating the soft parts intact. Another advantage is that the initial incision may be carried down under the spur along the junction of the floor of the nose and the ridge of the premaxilla. Elevation of the muco-periosteum can now be started from below and carried up to the point where the tissue is reflected to the other side. This barrier to further elevation may thenbe cut.

AT the meeting of the State Medical Society in May a resolution was adopted approving of the plan of holding a world's Panama exposition at New Orleans in 1915, and expressing the belief that a proper impetus would be given thereby to matters of sanitation. *Jour. Am. Med. Asso.*

THE USE OF TUBERCULIN AT THE SHARON SANATORIUM.*

BY WALTER A. GRIFFIN, M.D.,
Resident Physician, Sharon, Mass., Sanatorium.

TUBERCULIN has been used at the Sharon Sanatorium for diagnostic purposes for eight years, and as a therapeutic measure for five years. One hundred and nineteen cases have been tested by it, and 36 have had it as treatment. Of this number, 44 have been discharged less than a year ago from the sanatorium, and these will not be considered, since this report is intended to be, in part, a record of the present condition of those patients who have received tuberculin. This leaves, then, to be considered, 83 cases who have been tested and 28 who have been treated.

Of the tested cases, 4 are known to have died, but only one of these died of tuberculosis. There can be no reason to suppose, however, that the giving of tuberculin hastened her end in any way, since she left the sanatorium in good condition and worked as a nurse for eight years. In fact, she was in charge of a case the week before her death, which resulted, as far as can be learned, from hempotysis. Of no other case can there be raised the suspicion of any detriment from the test. The usual procedure has been in each case to give 2 mgm. the first time, followed, in case no reaction occurred, by 5 mgm. and 10 mgm. Eight cases failed to give a reaction with 10 mgm. and were discharged "apparently well." They all showed suspicious signs in the chest, and one in particular had a well-marked area in the base of the right lung where there was dullness, diminished respiration and moist râles. The sputa, which were rather free at times, never contained tubercle bacilli, but always contained pneumococci in abundance. Since discharge she has been working as a domestic for four years. The signs in the chest have persisted without any increase and with no failure of the general health.

Our experience at Sharon would be, in brief, that it is wise and safe to test all cases with signs in the chest who do not present tubercle bacilli in the sputa, using for this test the subcutaneous method. This makes possible the best use of a sanatorium for incipient cases, for it should be, namely, a place where doubtful cases may be sent and tested for tuberculosis. If disease is found, a cure should be begun and the patient should be taught sanatorium methods. Neither does there seem to us any harm in using as high a dose as 10 mgm., since, when this dose is worked up to gradually, it does not cause a severe reaction. And, further, if a less dose were taken as the limit of use, some cases would fail to be detected who might need sanatorium treatment. The following table shows the dose required to establish the diagnosis in the whole 83 cases.

1 milligram,	1 case
2 milligrams,	12 cases
3 "	3 "
4 "	4 "
5 "	35 "
8 milligrams,	1 case
10 "	12 cases
Cutaneous and general,	1 case
Before entrance,	3 cases
10 milligrams, negative,	8 "
7 " "	1 case
5 " "	2 cases
	83 cases

Treatment with tuberculin was begun rather experimentally on 3 cases who were moderately advanced and who had apparently come to a standstill in their improvement under general hygienic conditions. They seemed peculiarly fitted, therefore, to test the value of some treatment in addition to the regular sanatorium régime. The first patient was admitted April 20, 1903. There were well-marked signs all over the left side of the chest and at the top of the right. The sputa contained many tubercle bacilli. With ordinary sanatorium treatment the cough and expectoration ceased and the weight increased 42 lb. She was discharged at the end of eight months with disease arrested. Within a year she was back with renewed cough and expectoration and as bad general condition as at the time of first admission. For five months the physical signs and general condition remained about the same. Bacilli could be demonstrated in the sputa at any time. Finally, since there had been no appreciable change since entrance, Dr. Bowditch decided to try tuberculin, which was given for five months, and under its exhibition the cough and expectoration ceased and the physical signs improved to a marked degree. Since discharge she has had to work at intervals in rather unsanitary surroundings. In spite of this she has kept in good condition, now five years after discharge. The second case had been in the sanatorium three and a half months when tuberculin treatment was started. The weight had improved a little, but all other symptoms had increased. The extent of disease in the chest was greater, the cough was more frequent, the expectoration more copious, the temperature had begun to go up in the afternoon and the voice had become husky, the larynx showing definite inflammatory changes. Treatment was continued for seven and a half months. She was discharged in excellent condition and she now boasts that she feels perfectly well and has not seen a doctor since she went home in December, 1905. The third case first received tuberculin after a stay of six months, and treatment was extended over seven months. Improvement was but slight and the subsequent history has not been good, although the patient is still alive. These first three cases were so encouraging that each year more have been given tuberculin treatment, until at present there are ten having it, or nearly half the capacity of the sanatorium.

In all cases either old tuberculin or bouillon filtrate have been used. These products are probably safer than some of the others and the results in our hands and in the hands of other observers seem as good as with any other tuberculin. Each investigator has large claims for his own methods of manufacture, but no one has as

* Read before the American Climatological Association, May 5, 1910.

Stage (Turban).	Number.		Apparently Cured. (Per Cent.)		Arrested. (Per Cent.)		Improved. (Per Cent.)		Unimproved. (Per Cent.)	
	Tr.	Untr.	Tr.	Untr.	Tr.	Untr.	Tr.	Untr.	Tr.	Untr.

III	2	10	0	0	0	0	0	30	100	70

yet found the perfect product nor, in fact, any that gives better apparent results than old tuberculin and bouillon filtrate. With our own cases those who have received old tuberculin have shown no apparent difference to those who have received bouillon filtrate.

Of the 28 cases who haye received the treatment, 6 have died. Two of these were far advanced at the start and were given injections at their own request. Three others who were not favorable cases were given tuberculin on the chance that it might help when all probibility of help by ordinary means seemed futile. The sixth case did well and left the sanatorium in good condition, dying about a year later of a sudden hemoptysis. Two others of the 28 returned to a poor environment, contrary to advice, and are not doing well. Two more have relapsed in spite of care. These last cases may improve in the future, and from what can be learned they are certainly not hopelessly sick. This leaves 18 who are in good condition, — an encouraging record, it seems to us, when it is understood that all but 5 cases were more than incipient, and all but 3 had tubercule bacilli in the sputa. The above table shows the condition and result of treatment of all cases discharged between May 1, 1905, and May 1, 1909.

It might appear from this that more cases could be apparently cured in Stage 1 without tuberculin, but the majority of the 61% untreated in this class were given tuberculin as a test, and such cases usually can be discharged "apparently cured" whatever treatment is instituted. It might be argued that test cases are most suitable for treatment, since they would practically always be able to take treatment without disagreeable effects manifesting themselves, and they would be made as resistant to tuberculosis as possible by any means now at our disposal.

From our experience at Sharon, both Dr. Bowditch and I feel that tuberculin when carefully given is not likely to do any harm and that it frequently is of great benefit, affecting a cure in some cases that would not be expected to do well under ordinary methods of treatment, and, finally, that no cases of frank tuberculosis should be denied the privilege of tuberculin treatment if they desire to have it.

Reports of Societies.

RHODE ISLAND MEDICAL SOCIETY.

On May 17, 1910, the Rhode Island Medical Society elected the following officers for the ensuing year: President, Dr. Augustine A. Mann, Central Falls; First Vice-President, Dr. Frederick T. Rogers, Providence; Second Vice-President, Dr. Alexander B. Briggs, Ashway; Secretary, Dr. Stephen A. Welch, Providence; Treasurer, Dr. Winthrop A. Risk, Providence; Committee of Arrangements, Drs. A. A. Barrows, J. B. Ferguson and F. E. Burdick; Committee on Legislation, Drs. G. T. Swarts, W. F. Gleason, W. L. Munro, the president and secretary *ex-officio;* Committee on the Library, Drs. Day, Hersey, Collins, G. S. Mathews and Partridge; Committee on Publication, Drs. G. D. Hersey, C. M. Godding and G. S. Mathews; Curator, Wm. J. McCaw; Committee on Necrology, Drs. E. E. Pierce, Adrian Mathews and G. T. Spicer; Alternate Delegate to the House of Delegates of the A. M. A. for 1910 and 1911, Dr. Wm. B. Cutts; Auditor for two years, Dr. F. T. Fulton. The president appointed the following committees: On Building, Drs. J. W. Mitchell, R. F. Noyes, F. T. Rogers, F. H. Peckham and J. M. Peters; on Medical Education for three years, Dr. G. T. Swarts.

The treasurer reported that a special fund of $5,000 had been received from the estate of the late Dr. Horace G. Miller, which fund is to be used to maintain the ophthalmological library.

The annual report of the secretary showed that the society numbered 384 members, divided as follows: Resident, 345, non-resident 27 and honorary 12.

For the committee on legislation, Dr. G. T. Swarts introduced the following resolutions, which were unanimously adopted:

Resolved, That the Rhode Island Medical Society endorses the purposes of the Owens Bill now before the U. S. Senate, which provides for a Department of Health and urges upon the Senators and Representatives in Congress from the State of Rhode Island that they bring every influence to bear for its passage.

Resolved, That a copy of this resolution be forwarded to each member of Congress from this state.

At the annual session, held May 31, 1910, announcement was made that two Fellows had died since the last meeting: Drs. George F. J. King on April 12, 1910, of pneumonia, and George H. Kenyon on May 7, 1910, of nephritis.

Additions have been as follows: Dr. John E. Duffy, Natick; Dr. Harry V. Carroll, Newport; Drs. Peter W. Hess and Charles H. Holt, Pawtucket; Drs. Frank M. Adams, Harold G. Calder and Alfred W. Love, Providence, and Dr. James A. King, Woonsocket.

The Caleb Fisk Fund prize of $200 for the best essay on the subject, "The Classification and Treatment of the Diseases Commonly Known as Rheumatism," was awarded to Dr. Frank E. Peckham, of Providence.

In 1911 a prize of $200 is offered for the best essay on the subject of "Vaccine Therapy."

For the year ending May 1, 1911, a Chase-Wiggin Fund prize of $90 is offered for the best essay on the subject, "Tobacco, and its Evil Effects in All Its Forms on Those Who Habitually Use It."

The following is an abstract of the addresses and papers.

THE ANNUAL ADDRESS OF THE PRESIDENT, DR. EUGENE KINGMAN, PROVIDENCE.

There is a universal law of growth and achievement. The man who knows himself, understands his own powers and aptitudes, forms purposes in accord with them and pursues these purposes steadily is the man of success. Thus says Francis Parkman.

So this society must know itself. By a provision of our charter we can hold property, a body politic and corporate. "Men may come and men may go, but [we can] go on forever." In part we have accomplished the purposes for which this society was created. Directly or indirectly we have taken part in the creation and adminstration of health boards, the founding and serving of hospitals, the improvement of food, the restraint of disease and the enactment of wise medical laws.

We have done something to advance the art of medicine by our prizes and publications.

Much attention is paid to-day to the conservation of our national resources, and the greatest resource of all, the national health, until recent times comparatively neglected in the rapid material development of the country, is gradually assuming a place of the first importance in the public mind and conscience. Our society, perhaps the most important factor in the conservation of the health of Rhode Island, and its needs, is my subject to-day. We have two great needs: first, a home; second, money.

For ninety-eight years we have wandered from place to place, hiring whatever hall we could get. We need a place for a library, some thirty thousand books, including several complete and valuable files of medical journals.

We need a large amount of money to further the purposes for which the society was founded. We need a building with its assembly and committee rooms, a salaried librarian and a book delivery system. We should have a complete laboratory and the services of a pathologist day and night.

We should be able to employ eminent counsel to draft just medical laws.

We should be able to pay certain chairmen of our committees to give all their time to the committees. We should have an emergency fund.

Legislators are sometimes slow, and quick relief of impending evil often seems impossible. The amount needed is too large to be raised from members of this society. Physicians, as you well know, with few exceptions, after giving of their time and money to various charities, and paying their living expenses, have too little left to contribute largely to this cause. The endowment must come chiefly from the public and when the community understands that our work is to improve the physician, advance our art and help the people, they will in time respond generously.

Is it too much to foretell, that in two years we shall celebrate our centennial in our own building?

THE TONSILS.

Dr. Harlan P. Abbott, Providence. The tonsillar ring of Walderyer comprises four lymphoid structures, the faucial tonsils, the lymphoid tissue in the naso-pharynx and the lymphoid tissue at the base of the tongue. When enlarged, these structures are named enlarged tonsils, adenoids and lingual tonsils. Like the appendix, the tonsils are thought by some to be vestiges of once useful organs.

The anatomy of all is much the same though the faucial tonsils are more highly developed than the pharyngeal or the lingual. They are masses of lymphoid tissue held together by a stroma of connective tissue. The exposed surfaces are covered by mucous membrane, which in places dips down deep into the body forming lacunæ. Beneath the lacunæ are rows of follicles. The investing fibrous capsule attaches the tonsil to the superior constrictor muscle. The faucial pillars in front and behind and the folds of mucous membrane above and below envelope the tonsil. These folds are important as they often cover up large lacunæ and prevent the escape of débris and bacteria lodged there.

The tonsils act as the first line of defense against bacteria.

When weakened by disease the tonsils are the portals by which bacteria gain entrance, passing the epithelial lining and through the parenchyma to the lymphatics and blood vessels. These paths were pointed out in 1889 by Sir Andrew Clarke, who cited rheumatism as a possible result of such invasion. Since then numerous observers have recognised the tonsils as the entrance door for various diseases, setting up septic joint and endocardial disorders as well as tuberculosis.

Attempts are now being made to show that the tonsils when healthy have the function of taking care of the débris from neighboring organs.

The tonsils are more or less large up to puberty, when usually they subside to insignificant size.

Others are the source of frequent attacks of inflammation and enlargement, obstructing breathing, talking and eating; interfering with the circulation of neighboring organs as the Eustachian tubes and so interfering with the integrity and function of the ears. Chronic enlargement follows repeated inflammatory attacks and various children's diseases.

Hypertrophied tonsils are to be removed when obstructive symptoms are present. Diseased faucial tonsils should be removed *in toto*, capsule and all, unless the case is that of a bleeder.

Adenoids leading to ear disease, slow development and deformities also require removal. These adenoids may recur even when carefully removed.

In conclusion attention may be called to the following points:

1. That the tonsils are frequently the open avenue for local and general infection.
2. That simply because the tonsil is enlarged is not sufficient reason for removing it.
3. That the true function of the tonsil is still *sub judice*.
4. That the tonsil, as a rule, should not be removed when acutely inflamed.
5. That a diseased tonsil should be thoroughly eradicated, including the capsule.
6. That adenoids may return in young subjects even if they have been thoroughly removed.
7. That the operating surgeon should be prepared to control obstinate bleeding, primary or secondary.

THE EYE IN THE DIAGNOSIS OF GENERAL DISEASE.

Dr. Frederick T. Rogers, Providence: In this day when no diagnosis is complete without its laboratory findings, it may not be amiss to call attention to some elements of diagnosis which are not dependent on other than our own powers of observation. The eye is not to be relegated to the oculist; the general practitioner can recognize in it an important aid to diagnosis.

The general expression of the eye may afford us valuable information; the lids give evidence; the action of the muscles is significant.

On the conjunctiva hemorrhage in young people may show diabetes; in the aged, arteriosclerosis. The term

conjunctivitis is a sort of " catch all " for physicians. As a matter of experience there is a simple rule which will determine whether it is the conjunctiva, the iris, the sclera or the cornea which is affected. In conjunctivitis there is a disturbance of secretion without pain or photophobia; in corneal disease there is no increase of secretion but marked photophobia and subsequent pain, while in iritis there is a predominant pain and lacrimation and photophobia, dependent on the severity.

The form of conjunctivitis most infrequently recognized is the phlyctenular. This is frequently associated with disturbance of digestion. In children an improper amount of sweets, tea drinking or irregular eating is the cause. The color of the sclera, as in jaundice, chlorosis and nephritis, is significant. Scleritis accompanies gout, rheumatism, syphilis and intestinal intoxication. Keratitis, phlyctenular and ulcerative, shows struma, parenchymatous, in 75% of the cases of syphilis and the dendritic when associated with supraorbital tenderness, malaria.

Iritis is frequent with syphilis, gonorrhea, diabetes and rheumatism.

Paralysis of the muscles is shown by a squint or diplopia.

Which muscle is affected is shown by noting that it is always on the side where the doubling occurs and belongs to the eye that sees the object that appears most distant.

With knowledge of nerves and anastomoses we may decide extra- and intra-cranial lesions and location of lesions.

Von Graefe states that one third of all ocular palsies are specific.

The pupil has certain normal conditions and reactions, the departures from which are symptoms of disease. The findings of the ophthalmoscope are often indications of organic lesions. The means at our disposal of determining whether headache is or is not ocular in origin should be known to every one. Headache due to the eyes will show an affection of the lids and conjunctivæ secondary to errors of refraction as well as by disturbance of vision. The practitioner should use Snellen's chart and if the patient cannot read the letters at their proper distance may assume that the disease is defective vision.

Retinoscopy should also be known. In a dark room illumination of the eye at a distance of a meter shows a shadow which moves across the pupil. If the shadow moves with the mirror there is hypertrophia; if against it, myopia. If it moves faster in one meridian than in another, there is astigmatism.

Muscular anomolies are indicated simply by a test with red glass.

If one looks at a candle some distance off with a red glass over one eye, paralysis of one external muscle is shown by diplopia.

It there is functional paresis a strong cylindrical glass in front of either eye will throw a red image and a white bar of light.

In glaucoma a disturbance of the tension of the globe is frequently not recognized.

An address on " Graves Disease " was given by DR. JAMES G. MUMFORD, of Boston, and published in full on page 731 of this JOURNAL.

At the close of the session Dr. Augustine A. Mann was introduced as the president for the ensuing year.

The annual dinner followed, at which Dr. William F. Gleason was anniversary chairman. Dr. Timothy Leary of Boston spoke on " Immunity with Special Reference to Vaccine Therapy "; Hon. Edward F. McSweeney of Boston on " The Economic Aspect of the Treatment of Tuberculosis " and Dr. J. Alex Hutchison of Montreal gave an address.

THE AMERICAN NEUROLOGICAL ASSOCIATION.

THIRTY-SIXTH ANNUAL MEETING, MAY 2, 3 AND 4, 1910.

WEDNESDAY MORNING SESSION.

(Concluded from No. 3, p. 102.)

DR. ERNEST JONES, Toronto, Canada: It is too late to attempt to crush out Freud. The movement has already attained such dimensions that it can only be delayed; it cannot be crushed. There is now a large international society with sub-sections devoted to it. There are over two hundred trained workers in Denmark and Russia and Italy. There are four periodicals devoted to the work, besides the mass of literature that has appeared in the general neurological literature, and the movement has attained such dimensions that it has even reached England. It is perfectly easy with such startling principles as Freud formulates to form all sorts of excuses and pretexts which are not based on actual experience, which no one in this room has had excepting Dr. Putnam. Experience with the method is the only primal solution and the only primary criterion for the truth of these matters.

DR. JAMES J. PUTNAM, closing: Dr. Freud is one of the ablest and most intelligent physicians in Europe and one of the most honest and conscientious. His whole attitude towards the question was practically the same as the atittude of the various gentlemen who have spoken to-day. He simply then took up the fact which he had not invented, although his has been called by Dr. Knapp an hypothesis. It was never an hypothesis. It was a generalization upon the facts. They forced themselves upon his notice. He took them up in a thoroughly conscientious way, then dealt with them in an extraordinarily broad and scientific way. He brought them together with a thoroughness which no one can have any conception of. There is a great deal of misunderstanding of this sexual questioning. One does not take a young unmarried girl and begin to talk to her about her sexual relations. It would be very extraordinary if any one should do that. The sexual ideas are the ones the patient himself brings out. That Freud has always contended. If one had to summarize the value of this matter from the therapeutic side, the only word that fits the case is education. Dr. Mills spoke of the cruelty of trying to force patients into reviewing the things of which they are afraid; this would be true without explaining to them the nature of the enemy they had to meet. Of course as regards the length of time to which Dr. Sachs referred, that is not a criticism against the method; those who do not choose to spend the time, need not. We all of us spend vast amounts of time in studying the anatomy of the nervous system, and we are devoting ourselves to this study, to the anatomy of the mind. One is quite as justifiable as the other. Then again, the persons who speak as though the sexual thought were brought out in these patients' minds have failed to recognize that they are suffering from these thoughts, and the purpose is not to dwell on sexual thoughts, but to relieve their minds from sexual thoughts which in another form are active and producing symptoms.

As to the objection to the patient's probing himself, it is injurious to him to probe himself alone, and it is to prevent the patient from doing this that the patient is encouraged to probe himself before the physician; the patient probes himself alone from morning to night otherwise, and it is to make it impossible for him to do this that we use this treatment.

Dementia Precox Symposium.

The following paper by Dr. Smith Ely Jelliffe, New York City, was read by title, "Predementia Precox. The Hereditary and Constitutional Factors of the Dementia Precox Makeup."

THE GENERAL CONCEPTION OF DEMENTIA PRECOX.

Dr. Adolf Meyer, New York: Kraepelin created the picture of dementia precox under a set principle of nosology, with general paralysis as the paradigma: each disease has its specific lesion, and a true clinical entity has its unity of cause, course and outcome, and is necessarily the clinical picture of a unitary and specific lesion. General paralysis is indeed a specific disease-process best characterized by its lesions and by its definite syphilitic origin; but in dementia precox the nature of the lesion is not as decisive. The departure of our recent work consists in the surrender of nosological dogma for greater interest in the dynamic interpretation of the disorders out of the psychobiological material at hand as preferable to a dogmatic assumption of a hypothetical unitary toxic principle. The studies of metabolism and toxic states so far furnish nothing specific or decisive in regard to dementia precox. The neurological and histological data appear rather as incidental to more clearly definable functional data than with a leading rôle. The data of conduct and behavior and of reactive material of the patients have proved much more directly helpful in furnishing constructive material. The etiological constellations are necessarily complex. According to the makeup, the same results may be reached by combinations of marked constitutional peculiarity and slight external cause, and slight over constitutional peculiarities and marked external cause. The essential is the break of compensation of mental (chiefly emotional and volitional) adjustment with more or less deficit, and in most cases with the peculiar attempts at balance and reconstruction which constitute the glaring surface-picture of the clinical description and the special mechanism of the analytical consideration. The main question is, of course, whether the psychobiological estimates make it possible to distinguish differences of individual risks and prognosis, which would be preferable to the wholesale prognostication under an excessively broad "disease entity." Evidence seems to favor the postulate of a departure from the Kraepelinian dogma. Dementia precox is essentially unlike general paralysis and more like the usually inevitable outcome of (1) conflicts of instincts and (2) incapacity for a harmless constructive adjustment.

ON SOME OF THE MENTAL MECHANISMS IN DEMENTIA PRECOX.

Dr. August Hoch, New York: The topic assigned to me in the symposium was the symptomatology of dementia precox from the point of view of the content of the psychosis. In certain paranoic states, such as those described by Rüdin and Gaupp, also in a certain type of psychosis recently analyzed by Birnbaum, the content of the psychoses represents conflicts and reactions to conflicts which the individual, owing to a constitutional defect, was incapable of handling adequately. The clinical picture of dementia precox is much more complicated and often presents apparently a disconnected array of manifestations. When it is possible to analyze these, however, it is found that all the experiences mean something to the patient; that certain Freud mechanisms are at work, and that these apparently disconnected symptoms are connected and related to definite trends. The frequency with which sexual conflicts are found in the history of such patients and the fact that so often sexual trends make up the content of the psychosis point to a lack of sexual adaptation. Our memories are grouped, as it were, in more or less extensive and more or less circumscribed complexes or centers of attraction, in the formation and cohesion of which special interests take an important part. We can conceive of the mind, therefore, as made up essentially of trends of interest. In the course of individual development certain main tendencies of the personality develop which then take the lead, while other tendencies become repressed. These repressed trends exert, nevertheless, a marked influence on the conscious thought and activity, as Freud has shown; but in normal life they do so mainly through the fact that the energy they supply is led into profitable channels. Every trend naturally pushes towards a realization in the direction of its feelings. If this is in harmony with the main tendencies of the personality, this is useful and represents the dynamic force behind our thinking and our pursuits, adapted to the environment and the given situation. If, however, trends which are not in harmony with the main tendencies of the personality, and which are, therefore, under the influence of repression, no longer find an outlet in profitable channels, but assume a more or less independent dominating rôle, it is not to be supposed that the laws which govern normal mental activity should be suspended; on the contrary, we shall expect to find the same principle of the trend pushing towards its realization, while at the same time the other tendencies of the personality assert themselves in repressing influences as well as in adjustment reactions, but, owing to the disturbances of balance between the usurping trend and the main tendencies of the personality, the thinking and acting is then no longer adapted to the actual situation, but appears as something strikingly out of contact with it, and is of a simpler, more crude type. This, in so far as the mental side is concerned, is what seems to take place in the cases of dementia precox which can be analyzed—the overgrowth of certain trends at the expense of the main, adapted interests of the personality.

Wednesday Afternoon Session.

The meeting was called to order at 2.45 P.M. by the President, Dr. Morton Prince, Boston.

A STUDY OF ERRORS IN THE DIAGNOSIS OF MENTAL DISEASE.

Dr. E. E. Southard, Boston: A series of 250 cases of mental disease, with *intra-vitam* diagnoses by several physicians, recorded at the Danvers State Hospital daily clinics, 1904–8, has been subjected to anatomical review for the sake of learning where lie the greatest difficulties in diagnosis. Ten cases (4%) remain both clinically and anatomically obscure. Seven cases (2.8%) had diagnostic doubts settled after the clinic either *intra-vitam* or *post mortem* (1 case each of general paresis, cortical arteriosclerosis, cerebral sclerosis with Graves' disease, streptococcus septicemia, epilepsy, streptococcus meningitis, cerebellar abscess). Sixty-six cases (26%) were doubtful clinically, but the correct diagnosis was obtained by one or more diagnosticians in 49 of the 66 (74% of the doubtful group); 184 cases (74%) were clinically certain, and the clinical diagnoses were confirmed (or not altered) by autopsy in 163 of the 184 (89% of the unanimous groups). The correct diagnosis was obtained by one or more diagnosticians in 49+163=212 cases in 250 (85%). The "correctness" of these diagnoses is subject to some reservation, (1) since within the "organic and senile dementia group" differentiation proved difficult, and (2) since anatomical "consistency" often

signifies absence of characteristic lesions. The acute psychoses have been reviewed, however, bearing in mind modern views. Several alcoholic cases failed to exhibit striking brain lesions. The majority of the real diagnostic difficulties uncovered by this analysis would appear to require more intensive work in the field of clinical pathology. For such work in psychopathic hospitals, this paper is an appeal.

DR. COTTON, Trenton, N. J.: The question of error is one that is very important, and error in diagnosis is one that cannot always be averted; however, at Trenton we find that by presenting the cases twice at staff meetings the errors have been reduced very much. We take up the cases that come to autopsy, correlate them with the clinical diagnosis, and give the results the benefit of the staff. This acts as a stimulus to each man and shows errors both in physical diagnosis and mental diagnosis. The therapeutics could be improved by having a more correct diagnosis. I know of nothing more serviceable to clear up diagnosis than lumbar puncture. If we take it up in organic and functional cases that are at all suspicious, the negative findings in everything except general paralysis make it a very important factor in arriving at correct diagnosis.

ON THE DIFFERENTIATIVES OF DEMENTIA PRECOX AND DEPRESSED STATES BY SO-CALLED BIOLOGICAL BLOOD TESTS.

DR. ELLEN CORSON WHITE and S. D. W. LUDLUM, Philadelphia: While the Wassermann reaction is of greatest value in differentiating syphilis and non-syphilitic diseases of the nervous system, it does not permit of further differentiation in so-called functional nervous diseases. Recently Much published a method by which he believed he could differentiate dementia precox and manic-depressive disease from other disease; the method is based on the inhibiting action of blood serum in cobra hemolysis. His results have not been confirmed by others. We wish briefly to state that we seem to have been able to differentiate between dementia precox on the one hand and melancholia on the other. Our method is based on the determination of the fixation of complement of guinea-pig serum by the serum of the patient. We found in melancholia that the amount of complement absorbed is very much larger than of all other diseases that we have studied, and also much larger than dementia precox, in which disease it is approximately normal. We have tested 67 cases of various mental diseases. Thirty-seven melancholics of manic-depressive type and involutional forms have so far been decisive and characteristic in all cases examined. We also found by carefully standardizing the factors in Much's test that it gave a positive test only in dementia precox. When the standardization was not done, a positive result was often obtained. The syphilitic cases, of course, can be separated by the Wassermann reaction and progress in biological tests is making it possible to discover chemical changes in so-called functional diseases.

THE CLINICAL SIGNIFICANCE OF THE URINE IN "NERVOUSNESS."

DR. EDWARD B. ANGELL, Rochester, N. Y.: I have noted for a number of years in examination of urine of patients afflicted with "nervousness" that in making the Heller nitric acid ring test there is formed at the junction of the urine and acid a pigment ring which varies in color from bright red to dark brown. Of the chemical nature of this ring I am unable to give any account, but believe I am safe in saying that it probably consists of some of the organic nitrogen compounds. It is a reaction entirely different from that given by indican or bile, although these substances may be associated. A similar reaction occurs in cases of ex-ophthalmic goiter and in those taking iodide of potash. That it is associated with excessive nitrogen elimination is shown by the fact that it is almost never present on a non-proteid diet. The patients who show this reaction are those who complain of headache, backache, restlessness, sleeplessness, numbness and a general, depressed feeling, associated with other symptoms generally classed as nervous. If such cases are put on a diet low in nitrogen, lead an open air life and are given salicylates and alkalies to aid elimination, they will be relieved of their symptoms and at the same time this reaction of the urine will disappear. From two weeks to two months are required for a cure. In obstinate cases a year may be required.

DISCUSSION.

DR. EDWARD D. FISHER, New York City: It seems to me that Dr. Angell has given us a rather easy clinical method of diagnosis. If we can find this ring, as he evidently has found it so frequently, a thing that can be done very readily in our offices, it will aid us at least in determining whether our cases are organic or functional. I would endorse very emphatically the point that Dr. Angell brought out, that there is very frequently a physical cause for many mental symptoms. The treatment as he has outlined it is one which I have long carried out in cases of neurasthenia, but we often do it in a wavering way. Now that we have a positive diagnosis of the metabolic changes which are going on, we will be encouraged to be more systematic in our medical treatment of these cases.

RADICULITIS OF CERVICAL AND BRACHIAL PLEXUSES, SECONDARY TO PACHY-MENINGITIS EXTERNA CERVICALIS GUMMATOSA.

DR. F. W. LANGDON, of Cincinnati: A white man of thirty-three, married, healthy children. Occupation, superintending outdoor work, grading, etc. Gradually developed a paralysis of tetraplegic distribution, beginning in left forearm and hand, and extending in the course of fourteen months so as to render useless all four extremities. The upper extremities were flaccid, the lower spastic, with plus knee-jerks and Babinski sign. The paralysis was preceded by sharp pains in left neck and face. Neck movements were almost abolished,—not by paralysis of muscles, but by articular obstruction. Numbness and tingling were extensively distributed over both arms and legs. A smooth, firm, not bony, boss could be felt in the left side of the neck between the third and fourth cervical vertebræ. The patient was unable to walk without constant danger of falling and was unable to grasp a pencil with either hand. Vision was good; pupillary changes slight; ocular movements free, with slight nystagmoid jerking on extreme lateral excursion. Some dysphagia at times. No voice or tongue changes. Sensory changes slight, excepting the initial pain in the left neck and face, which was not prominent after the first month. There was a hand-size area of tactile anesthesia over the left thorax and one twice as large over the right abdomen, where temperature sense was disturbed or confused. Diagnosis was made of an exudate (gumma) situated between cervical dura and periosteum enclosing the nerve roots and compressing the lateral columns of cord; a radiculitis and compression myelitis, secondary to pachymeningitis externa. Under mercury by inunction and supporting measures steady improvement occurred and patient was discharged at his own request in five and one-half months, having gained 25 lb. in flesh, and the use of all ex-

tremities. Three months later he resumed his regular occupation. A year later is able-bodied, can use pick and shovel well whenever necessary and attends to his full duties in every respect.

FURTHER OBSERVATIONS ON THE OCULAR CHANGES IN GENERAL PARESIS AND TABES DORSALIS.

Dr. Edward D. Fisher, New York: In the examination of 50 cases of general paresis both of the tibic and cerebral type, the writer confirms a former statement made in a paper read before the American Medical Association in 1909 that optic atrophy and ocular muscle paralysis are comparatively rare in general paresis as compared to their frequency in tabes; nor again are the muscular paralyses permanent, as a rule. Clinically this would seem to mark out the two diseases as distinct. In the 50 cases, only 2 had optic atrophy, and none any third nerve lesion outside of the Argyll-Robertson pupil. In the cerebral type of general paresis, that is, those cases of exaggerated reflexes, the Argyll-Robertson pupil is often absent in the early stages. Among over 200 cases of general paresis, only one presented a history of tabes extending over a number of years preceding the mental symptoms with the lightning pains, crises and ataxia.

LENTICULAR ZONE AND ANARTHRIA.

Dr. Alfred Gordon, Philadelphia: The anatomo-clinical case which I report shows that Marie's contention in regard to aphasia cannot be entirely confirmed by the pathological findings. The destruction of the lenticulo-caudate nuclei was complete and yet the patient did not present the least indication of anarthria or dysarthria. The speech was clear and distinct. The patient did, however, present a partial word-blindness and partial verbal amnesia, all symptoms of sensory aphasia. The few symptoms of the latter correspond to Marie's ideas. The conclusion to which my observation leads is that, while the so-called lenticular zone of Marie may play a certain rôle in sensory aphasia, its rôle is not considerable. As to its being a center for anarthria, the present case proves that its destruction does not interfere with phonation and articulation of words.

Book Reviews.

A Textbook of Diseases of the Ear. By Macleod Yearsley, F.R.C.S., Senior Surgeon to Royal Ear Hospital; Medical Inspector to London County Council Deaf Schools; Lecturer on Anatomy and Physiology to the Training College for Teachers of the Deaf, Ealing, etc. Chicago: Chicago Medical Book Company. 1908.

The writer states in his preface that his book has been written upon the lines of his smaller work on "Common Diseases of the Ear," but with considerable additions and extensions. It has been his aim throughout to give as complete an account as possible of the various diseases and injuries to which the organ of hearing is liable, and in as concise a form as is compatible with clearness.

The book contains fifteen chapters. The first deals with anatomy and physiology, and the last with the medico-legal aspects of otology and the bearing of ear diseases on life insurance. The intervening chapters cover in an orderly and systematic manner the whole field of otology.

This is a most satisfactory book. The text is clear and up to date. There is a grateful scholarly air throughout and combined with this there is a crispness and sureness in the many tables and summaries which make them convincing and satisfying. On this account the book should be very useful to the bewildered student of the larger textbooks and to the jaded practitioner.

It is especially pleasant to meet with an author who has the courage of his convictions in dealing with the complicated and antiquated nomenclature of ear diseases. For instance, the writer divides catarrhal diseases of the ear into two forms, namely: Catarrhal inflammation and otosclerosis. Suppurative diseases are as simply and as logically divided, namely: Injuries and acute diseases of the middle ear, and chronic suppuration and its complications. Students of otology who get their first ideas of ear diseases from this book cannot appreciate their good fortune in having this simple and evident classification set before them.

The book is small and well printed. The paragraphing is restful to the eye and the summaries are restful to the brain. The book would be better for a few more illustrations and for the substitution of line engravings for some of the muddled photographs.

The Water Supply, Sewerage and Plumbing of Modern City Buildings. By William Paul Gerard, C.E., Member American Society of Mechanical Engineers. Pp. 491. With 214 text illustrations, 15 tables and 25 diagrams. New York: John Wiley & Sons. 1909.

This new volume by Mr. Gerhard contains in a revised form various articles and lectures on "the water supply of buildings" and on "plumbing" which he prepared for engineering societies and technical journals. It presents the essentials of sanitary and hydraulic work as applied to modern city buildings, discusses and illustrates sanitary fixtures and appliances, explains plumbing methods, deals with the maintenance of pipe systems for water, sewage and gas, and contains a set of rules representing the best modern practise regarding plumbing, water supply and sewerage, chiefly with reference to hospitals and large public institutions. It also deals with plumbing in its relation to preventable disease. One of the various helpful features is the preparation under fifteen main headings of several hundred "reminders" regarding the materials, fixtures, workmanship and general contract conditions which will be found useful in the preparation of plumbing specifications.

The book deals with the subject from a practical standpoint and is designed for the use of architects, building superintendents, sanitary engineers, sanitary inspectors and health officers. It is an important contribution to the literature on the subject. The cuts and illustrations and the tables and diagrams relating to water mains, surface pipes, house sewers and kindred subjects add to its value and attractiveness.

Arthritis Deformans. By R. LLEWELLYN JONES, M.B. London: Wm. Wood & Co. 1910.

This work is an excellent presentation of the more modern views on the nature and treatment of the group of disorders to which the general term "arthritis deformans" can be applied, including, according to the author's classification, under this head two large groups: (1) Rheumatoid arthritis; (2) osteo-arthritis. He admits localized varieties of the latter, such as heberden nodes, spondylitis deformans, and adds a special chapter on arthritis deformans in children, among whom the so-called rheumatoid arthritis (Still's disease) is the more common.

The conclusions of the writer are based on careful reading of recent German, English and American literature and presumably an extended experience as he formerly served as medical officer of the Royal Mineral Water Hospital at Bath.

There is little that is original in the work, which is judicious in view of the fact that the writer has not had a large pathological material at his disposal, nor experimental laboratory investigation on which to base speculation. He has confined himself to a plain statement of current views sensibly presented with the conclusions which seem justified. The book is admirably illustrated.

The Diseases of Infancy and Childhood. Designed for the Use of Students and Practitioners of Medicine. By HENRY KOPLIK, M.D., Attending Physician to the Mount Sinai Hospital; Consulting Physician to the Hospital for Deformities; formerly Attending Physician to the Good Samaritan Dispensary, the St. John's Guild Hospitals, New York; ex-President of the American Pediatric Society; Member of the Association of American Physicians and of the New York Academy of Medicine. Third edition, revised and enlarged. Illustrated with 204 engravings and 39 plates in color and monochrome. Pp. 944. New York and Philadelphia: Lea & Febiger. 1910.

This, the third edition of this admirable and well-known work, has been thoroughly revised, considerably enlarged by the addition of new material and brought fairly well up to date. We note, however, that no reference is made to animal sera or transfusion in the treatment of hemorrhage in the new-born or in purpura, of bacterial vaccines in the treatment of pyelitis, or of the operative treatment of cerebral hemorrhage in the newborn. It is not reasonable, however, to note omissions or to discuss moot points when considering a book as good as this one, which ranks among the best in English on pediatrics. It will well repay careful perusal by both the specialist and the general practitioner.

The Elements of Hygiene for Schools. Compiled by ISABEL MCISAAC, late Superintendent of the Illinois Training School for Nurses. Pp. 172. New York: The Macmillan Company. 1909.

A creditable compilation of materials from textbooks on bacteriology, hygiene and sanitation by some of the ablest authorities for the use of teachers and children in our public schools. The chapters on school hygiene and disinfection are especially commendable.

As to what extent the book is adapted as a textbook for the use of pupils in the different grades there is some question, but as to its value for the use of teachers, superintendents of schools, members of school committees and school physicians, there can be no doubt. The book is illustrated and attractively printed; it deserves wide circulation.

Mendel's Principles of Heredity. By W. BATESON, M.A., F.R.S., V.M.H., Fellow St. John's College; Professor of Biology in the University of Cambridge. Cambridge: University Press. 1909.

The significance of Mendel's theory of heredity is increasing year by year as investigation progresses. The object of the book before us is to give a brief account of Mendel's researches and the results of his method as applied to the general theory of heredity. To accomplish this result Mendel's two important papers are translated, together with a biographical note. In addition to a general statement of the theory, Bateson has added a chapter on the practical applications of the Mendelian principles, which, in his opinion, are far wider than we can as yet perceive in relation to the breeding of plants and animals, and possibly ultimately in the control of the human race. On this basis an admirable book has been written containing an excellent bibliography and exceptionally beautiful illustrations in color. The book is certainly a welcome addition to the large number already existing on the subject of heredity, particularly as placing before a wide circle of readers a clear presentation of a doctrine not altogether simple to the uninitiated. The volume is admirably printed and arranged as is to be expected from the place of its publication.

The Harvey Lectures. Delivered under the auspices of the Harvey Society of New York, 1907–8. By Professors EDWIN O. JORDAN, JAMES EWING, DAVID L. EDSALL, ERNEST H. STARLING, GEORGE CRILE, JOSEPH JASTROW, OTTO FOLIN, ROSS G. HARRISON, E. A. SCHÄFER, ALONZO E. TAYLOR. Philadelphia and London: J. B. Lippincott Company. 1909.

This third volume of the lectures of the Harvey Society presents the work of ten recognized experts in the special subjects of present medical and scientific interest in which they may be regarded as authorities. In such a collection of essays it is almost invidious to select. It seems, however, that the chapters on "Cancer Problems," "Surgical Shock," "On the Trail of the Subconscious," "Embryonic Transplantation and the Development of the Nervous System" and "Artificial Respiration in Man" are likely to prove of the greatest range of appeal. The volume is one which merits thorough and thoughtful reading both by physicians and by the educated laity.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JULY 28, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 Tremont Street, Boston, Mass.

CHILD SUICIDES.

Many of our readers have noted the recent comments on the case of the lad of fourteen years, at the Lyman School for Boys at Westborough, Mass., who ran away from the institution, was promptly brought back again and placed in a detention-room and was discovered, later, dead, suspended from an iron bar which ran across the window.

The most obvious explanation of the death was suicide, and as this school has always enjoyed the highest reputation for following a liberal and progressive policy in the performance of its difficult task, this explanation will doubtless be held by most fair-minded persons until sufficient reasons are brought forward for a contrary opinion.

As might have been expected, however, the case has been utilized as a door for criticisms, allegations and suspicions on which we have no wish nor right to pass a judgment, but which are being reviewed by a committee of the General Court, from whom a report may shortly be expected. Meantime, the matter has a medical aspect which should not be overlooked. Few persons except the students of such subjects are aware how common suicides among children really are or in response to what trivial-seeming causes they are committed. This is especially true where the child is somewhat neurotic or eccentric, although the eccentricity may not seem to involve any greater lack of balance than would be covered by the term "romantic." This fact, among others, is brought out in an address by Professor Eulenburg, the prominent neurologist of Berlin (published in the *Zeitschrift für Pädagogische Psychologie*, etc., and reviewed briefly in the London *Lancet* for 1907, II, p. 328). It seems that between 1880 and 1903, 1,152 children took their lives in Prussia, and that "in about 10% of the cases no cause could be found. In some cases the motives of the suicide were rather trivial, such as the refusal of the parents to allow certain games or recreations." Every essay on the subject contains similar statements and only adds to the accumulating evidence that our knowledge of the child's mind is eminently incomplete. Thus Guthrie ("Functional Nervous Disorders in Childhood," London, 1907) says (p. 101): "Sometimes mere curiosity to see how it feels may lead to apparent attempts at suicide. A boy of nine was said to have attempted to hang himself, but I found on questioning his parents that, having been warned against the danger of putting his head in a round towel, he promptly did so, swung himself round, and nearly succeeded in strangling himself. . . . In September of the present year, 1906, a schoolboy of Hamburg, aged thirteen years and two months, committed suicide because after the summer holidays he was not moved from his former class into a higher class. He hanged himself from a peg on the wall of his bedroom."

In the course of a hearing before our National Legislature on the bill (H. R. 16733) to establish a laboratory for the study of the criminal, pauper and defective classes, a number of interesting statistics bearing on this subject were presented by the criminologist, Arthur Macdonald, a few of which are as follows: Table 8, compiled from official sources by A. Baer (p. 77 of the report), shows that the number of suicides in Prussia of children even under fifteen years of age increased pretty steadily from 31 in 1869 to 70 in 1898. In 1891 the total number ran up to 81. Similar statistics are reported from other countries. According to the United States census of 1900, the suicides in that year occurred as follows:*

Ages.	Suicides.
5 to 9	1
10 to 14	28
15 to 19	246
20 to 24	531
25 to 29	534
30 to 34	555
35 to 39	594
40 to 44	600
45 to 49	542
50 to 54	490
55 to 59	371
60 to 64	314
65 to 69	253
70 to 74	175

* This table is copied from the revised edition of the Reference Handbook of the Medical Sciences, vol. vii, article "Suicide."

Ages.	Suicides.
75 to 79	117
80 to 84	49
85 to 89	14
90 and over	5

Finally, reference may be made to a careful paper by Gustav Major, Director of the Erziehungsheims "Kinderschutz Berlin-Zehledorf,"[1] which is of especial interest because written from an educational standpoint.

The writer takes his statistics from the paper of Eulenburg above cited. Eulenburg had selected 284 cases for a special study, because reliable facts with regard to them could be obtained from school-directors, teachers, companions, relatives or physicians, etc., of the children, who were pupils in the schools of the higher grade. Of these 284 children, 29 had pronounced insanity and 51 more a feebleness of mental constitution (*Minderwertigkeit*). The next two groups, comprising respectively 67 and 68 children, were either peculiarly unfitted for school life or suffering from special defects of character and temperament, conditions which must frequently obtain among boys committed to a reform school because unmanageable at home. The last group, of 69 cases, is a portion of that which was referred to at the beginning of this paper, where no special cause of suicide could be found. But Major makes the just comment that a good half of these children were doubtless more or less abnormal. "Youth is the happy-go-lucky age of carelessness, of taking nothing seriously, of joyfulness and of excess; it is often, too, a period of emotional depression, but a healthy-minded child does not, after all, grasp at the revolver and the knife."

In his own estimate of causes Major points out how complex the situation is. The school, the home, and not only these, but many influences more that are brought to bear on the growing child as he passes through that marvelous and largely unchronicled period of transition from infancy to manhood must be considered by those who would deal fairly with this unfortunate situation. These influences lead to strong emotions on the one hand, and to repression of emotions, which must then find some new outlet, on the other hand. Child-suicide is painful to contemplate and yet must be contemplated, but the conditions which lie behind it are even more in need of careful study than the suicide itself. The fact is that the life of children is not the Elysium that it has been supposed to be, but a period of intense feelings and repressions, and often of black misapprehensions and emotions. These problems must be peculiarly difficult to meet in the case of a large school where boys are not only wayward, but whose waywardness is of many different sorts; not only unbalanced and excitable, but whose lack of balance appears under a great variety of forms. Each boy's case must be a special study in itself, and a study which has to be made under circumstances of great difficulty.

THE TRAINING OF HEALTH OFFICERS.

THE layman apparently takes more interest in preventive medicine than the physician; this, however, is more apparent than real, for the medical profession has never been more altruistic than at present. The medical man is just as keen for useful and fruitful results as the layman, but he sees the difficulties, and, therefore, has more patience with the snail-like progress which the "ounce of prevention" often takes.

One of the factors that has kept preventive medicine from reaping the full harvest in this country is the lack of trained leadership and the lack of trained men to fill the ranks. Perhaps the greatest handicap has come from mixing politics with public health administration. England has been a pioneer in establishing schools for its public health officials and demanding fitness as the first qualification. The health of England is guarded by a corps of sanitarians whose tenure of office is assured through effective civil service. Thus politics and public health have been divorced. The positions are sufficiently numerous, the pay sufficiently large and the tenure of office sufficiently secure to make the service attractive. The public health work of England has, therefore, had the benefit of specially trained men who devote their lives to this special field of science, and the results have been exceedingly satisfactory. Our own conditions contrast strangely. Here politics prevail; the positions are underpaid and the health departments undermanned; tenure of office is uncertain. The health officers in our country are seriously handicapped and as a consequence little impress has been made upon the great sanitary problems, such as typhoid and the other communicable diseases, infant mortality, industrial hygiene, the medical inspection of schools, the pollution of streams, the disposal of wastes and the collection of vital statistics.

The real estate agent, the gynecologist, the

lawyer, the engineer and even the general practitioner may make excellent health officers. Some of the ablest adminstrative officers in our country have been laymen, but the time has come when the sanitary sciences have grown so large and complex that their administration requires the services of a specialist. The lack of trained leadership in the public health affairs of our states and cities is glaringly apparent to those familiar with the conditions.

In order to fill this want Harvard University has taken an advanced step in offering the degree of Doctor of Public Health (D.P.H.). The object of this degree is to train men to fill executive positions in the various branches of the sanitary sciences, or to continue in laboratory research, or to teach the subject. Candidates for the degree are required to take post-graduate work, and the courses are broad and elastic enough to include the training of sanitary architects, sanitary engineers, sanitary chemists, vital statisticians and the other collateral branches as well as to cover the more strictly biologic side of the subject. What may be hoped from a university training is that a candidate may be given a thorough knowledge of the scientific foundations that underlie the subject, and the principles of its practical application. A student who has this knowledge plus the necessary inherent qualifications will have little difficulty in making good when it comes to the actual practise of his profession. If he lacks the inherent qualities necessary for success either through defects of temperament or looseness of moral perception, no training can equip such a man for large and useful achievement.

We feel confident that with the appearance of doctors of public health in the field, preventive medicine in this country will show distinct progress. The growth will be gradual, but in time a high standard of efficiency will be maintained in the public health departments of our states and cities. This, in turn, will result in the prevention of much unnecessary sickness, and the saving of many lives.

MEDICAL BIRTHDAY HONORS IN ENGLAND.

The recently published list of "birthday honors," containing the appointments made by King George V of England on the occasion of the day set apart for the commemoration of the birthday of his late Majesty, Edward VII, includes an exceptionally large number of distinctions conferred on members of the medical profession. The Right Honorable Sir Walter B. Foster, consulting physician to the Birmingham General Hospital, and emeritus professor of medicine at Queen's College, Birmingham, is created a baron of the United Kingdom. This is only the second instance in which a physician has been raised to the peerage in England, the first and only other creation being that of Lord Lister. The birthday list also names Francis Henry Champneys, Esq., M.D., as a baronet of the United Kingdom, and confers knighthood on eight prominent surgeons, among them Mr. John Lentaigne, F.R.C.S., of Dublin, visiting surgeon to the Mater Misericordiae Hospital in that city, consulting surgeon to the Royal Hospital for Incurables at Donnybrook, and surgeon to the household of the Lord Lieutenant of Ireland. In addition to these honors, the list gazettes the appointment of several military surgeons to the orders of the Bath, St. Michael and St. George, the Star of India, and the Indian Empire.

Commenting on this unusual recognition of the medical profession, an article in the London *Medical Press and Circular* regards such a liberal distribution of distinctions as evidence that King George and his government will take an appreciative interest in the progress of medical science, and considers that the presence of a medical peer in the House of Lords will result in the introduction and enactment of various beneficial legislative measures for the safeguarding and advancement of the public health. For the furtherance of the same object, the article also advocates a proposition for the collective maintenance of representative medical members in the House of Commons, where, for financial as well as professional reasons, there are at present but few physicians.

In considering these "birthday honors" from an American point of view, it must be remembered that, in the country in which they are conferred, they are intended and regarded as valuable and genuine distinctions, and, so far as they indicate public recognition of medical service, may be welcomed as a real mark of honor to the profession. Their worth will be the greater if they do afford opportunity for the progress of medical and hygienic reform in England.

ILLEGITIMACY IN FRANCE.

Vital statistics recently published in Paris show that, for a number of years, 11% of the annual births in France have been illegitimate,

and that the mortality of such illegitimate children is double that of legitimate children, partly from infanticide, largely from the conditions to which their infancy is exposed. In view of these facts, a bill has been introduced into the French Senate "abrogating two articles of the Civil Code which refuse to recognize the rights of an illegitimate child to the protection of its father," who is now not held responsible. It is interesting to note that the purport of the proposed bill is not so much to diminish illegitimacy as to reduce the death-rate of illegitimate children by compelling their fathers to provide them with adequate support. In connection with measures to check the declining French birth-rate, upon which we have made recent editorial comment, these considerations have special importance as presenting another aspect of the so-called "race suicide problem" in France, in which medical, ethical, social and economic factors are so intimately and intricately involved.

MEDICAL NOTES.

MEASURES AGAINST THE SPREAD OF BERI-BERI. — The Philippine government has forbidden the use in its institutions of the "polished rice," or rice freed from its outside covering. This covering contains phosphorus, the absence of which from the daily diet causes the disease.

CULLEN VICTORIA JUBILEE PRIZE. — The Cullen Victoria Jubilee Prize has recently been awarded by the Council of the Royal College of Physicians of Edinburgh to Dr. R. W. Philip, physician to the Edinburgh Royal Infirmary, "for his investigations and work in connection with consumption." This prize, which is of the value of £100, is awarded every fourth year for the "most important contribution to practical medicine."

BUBONIC PLAGUE IN TUNIS. — It is reported from Tunis that five cases of bubonic plague have recently occurred in that city, and that four of the patients, three natives and an Italian woman, have died. Examination of the house in which the fatal cases were found resulted in the discovery, under the floor of a verandah, of a large number of dead rats, from which it is believed the infection was derived. The strictest quarantine precautions were instituted to prevent furthur spread of the disease, and no more cases have as yet been reported.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.— For the week ending at noon, July 26, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 40, scarlatina 18, typhoid fever 11, measles 29, smallpox 0, tuberculosis 55.

The death-rate of the reported deaths for the week ending July 26, 1910, was 17.14.

BOSTON MORTALITY STATISTICS. —The total number of deaths reported to the Board of Health for the week ending Saturday, noon, July 16, 1910, was 221, against 163 the corresponding week of last year, showing an increase of 58 deaths and making the death-rate for the week 18.30. Of this number 115 were males and 106 were females; 217 were white and 4 colored; 143 were born in the United States, 75 in foreign countries and 3 unknown; 51 were of American parentage, 144 of foreign parentage and 26 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 38 cases and 3 deaths; scarlatina, 20 cases and 0 deaths; typhoid fever, 11 cases and 1 death; measles, 55 cases and 2 deaths; tuberculosis, 105 cases and 21 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 17, whooping cough 1, heart disease 24, bronchitis 1. There were 12 deaths from violent causes. The number of children who died under one year was 48; the number under five years, 67. The number of persons who died over sixty years of age was 54. The deaths in public institutions were 95.

Cerebrospinal meningitis, 1 case and 1 death.

Of the above infectious diseases the following were non-residents: Consumption, 17 cases and 3 deaths. Scarlet fever, 2 cases.

Deducting deaths of non-residents, the total is 191 and the death-rate is then 15.81.

A CENTENARIAN. — It is stated that Patrick O'Neil has died at Lowell, Mass., at the age of one hundred and two years.

A BOY SUICIDE. — Following close upon the presumed suicide of a boy at the Lyman School, a sixteen-year-old inmate of the Concord Reformatory has recently committed suicide by hanging. The whole subject of suicide among the young is discussed in our editorial columns.

EXTENSION OF BOSTON CITY HOSPITAL. — The trustees of the Boston City Hospital have purchased from Robert Treat Paine land on

Massachusetts and Harrison avenues and Northampton Street. Upon this will be erected, at a cost of about $165,000, a much-needed extension of the contagious department of the hospital.

A Possible New State Hospital. — It is announced that Governor Draper, of Massachusetts, has made nominations for a commission to consider the advisability of establishing a state hospital for cases of nervous disorder of mild degree. Among those nominated for this commission are Dr. William N. Bullard, of Boston, and Dr. B. R. Benner, of Lowell.

Dr. David W. Cheever, Surgeon Emeritus. — At a recent meeting of the trustees of the Boston City Hospital, resolutions were adopted on the long service of Dr. David W. Cheever as surgeon to the hospital. In these resolutions a statement was made of his long and devoted service to the hospital, his skill as a surgeon, his ability as a teacher and his remarkable clearness of diction.

Appointment of Seymour H. Stone. — Mr. Seymour H. Stone has been appointed secretary of the Boston Association for the Relief and Control of Tuberculosis. He succeeds in this office Mr. Alexander M. Wilson who, for many years, has been closely identified with the work against tuberculosis in this city as well as in Chicago. Mr. Wilson now goes to Philadelphia in connection with similar work in that city.

Bequests. — By the will of the late Mrs. Margaret W. Frothingham, of Cambridge, money is left to many charities. Among these the Cambridge Hospital and Cambridge Home for Aged People benefit in the sum of $1,000 each; the Kindergarten for the Blind in Boston and a Home for Aged Women in Charlestown in the sum of $500 each.

NEW YORK.

Death-Rate from Tuberculosis. — Walter F. Wilcox, consulting statistician to the State Health Department, having stated in the March number of the *Monthly Bulletin* that "no influence of the special campaign against tuberculosis can be traced in the figures of 1900 to 1908 inclusive," now reports that the totals for 1909 have been compiled with more cheering results. In the state outside of New York City the deaths from all causes except tuberculosis increased from 55,314 in 1900 to 59,529, an increase of 4,215; but during the same period the deaths from tuberculosis decreased by 22. This difference, Mr. Wilcox thinks, may be ascribed to the campaign against tuberculosis which has been carried on so energetically in the state since 1907. It would take some time, he says, for the campaign to influence the death-rate, and its effect would naturally be cumulative as facilities for the proper care of tuberculosis patients multiplied.

Infant Death-Rate. — The infant death-rate in the city continues unusually high. In the week ending July 9 it was 55% greater than in the corresponding week of last year, and in the week ending July 16, 75% greater. In the first of these weeks the number of deaths reported from diarrheal diseases in children under five years of age was 280, as against 160 in 1909, and in the second, 437, as against 246 in 1909.

2. Bulson believes that the Noguchi reaction is a distinct improvement over that of Wassermann, or any of the other methods, for the reason that it is not so complicated and is probably more accurate and delicate. He also feels that the test is going to prove of inestimable value to the ophthalmologist in diagnosing doubtful cases and giving indications for treatment.

3. McCoy states that by means of animal experimentation the cause of plague has been demonstrated; also the means by which it is conveyed in nature from animal to animal and from lower animals to man, and has showed us how to control outbreaks of the disease.

5. Corlett and Cole report three distinct epidemics of an anomalous scarlatina, of 32 cases, in which the important points of observation were, (1) a lack of or very slight presence of any exanthem; (2) desquamation, absent or occurring only over one small area, such as one buttock; (3) absence of any marked nephritic lesion; and (4) presence of severe angina in nearly every case.

9. Bowen, not minimizing vaccine treatment, suggests the following treatment in obstinate cases of furunculosis: (1) Wash whole body twice a day with warm water and soap; dry. (2) Bathe the whole body with a saturated solution of boracic acid in water; dry without wiping. (3) Dress the individual furuncles with the following:

Boracic acid,	℥i
Precipitated sulphur,	℥i
Carbolized petrolatum,	℥i

This has proved efficient in many cases when vaccines have not. [E. H. R.]

16. MCWILLIAMS, C. A. *Operations upon the Appendix.*

1. The changes in nerve cells in anemia, infections, Graves' disease and surgical shock recall changes in nerve cells in rest and activity found in animals by Hodge, Pugnat and others. In all conditions there is one general law of change — turgescence of the nucleus, loss of limiting membrane of nucleus and cell with consequent distortion and perhaps complete disorganization. The Nissl staining substance is at first increased and later diminished (hyperchromatic and chromatolytic stages). Ether damaged brain cells four times as much as nitrous oxide. If the hyperchromatic stage has passed and the chromatolytic stage has begun, the death of the cell is inevitable despite transfusions in case of hemorrhage, despite enteroenterostomy or resection in case of intestinal gangrene.

3. Levin has analyzed 4,000 cases of cancer (data obtained from twenty-three hospitals and twenty-seven physicians and surgeons), aiming at the primary causes, either constitutional or those of environment, and reported to stimulate similar effort throughout the country. *Sex:* More frequent in female owing to prevalence in uterus and breast, but the percentage of cancer of the mouth and digestive organs is greater in the male, with his greater use of tobacco, alcohol and coarser and more irregular diet. *Age:* The incidence of cancer varies somewhat with its situation; for instance, 48.5% of cancer of the extremities occurred under the age of thirty-four. *Childbearing* seemed to have no direct connection with the causation of cancer. *Occupation* plays important rôle (chimney sweeps, aniline workers, x-ray), but only certain number of workers contract the disease. It is rare among miners. Co-existence of syphilis, tuberculosis or arteriosclerosis was unusual. The latter seems to occur more commonly with cancer of head, face and neck (14.5%). The relation of cancer of the stomach to ulcer, of the gall bladder to stone, of the breast to mastitis and of the penis to balanitis is considered. Hereditary disposition was shown in so small a number that it is doubtful whether it has any influence on the occurrence of cancer. It appears that local trauma or previous disease of the affected organ is of less importance than the increased vulnerability and lessened resistence of the organism caused by strain of modern life.

6. Charles Mayo reports eight cases of esophageal diverticula. For diagnosis he recommends the esophagoscope, the x-ray of the bismuth-acacia-distended sac, and Plummer's method with thread and whalebone and olive-tips. Preliminary gastrostomy is not considered necessary. The use of the swallowed thread as a guide for the stomach tube has been practiced.

7. Finney reports a case of resection of the middle portion of the pancreas for cystadenoma with approximation of remaining portions with mattress sutures of catgut and iodoform drainage. This is the seventeenth reported case of operated primary tumor of the pancreas, and the third in which the gland has been divided and sutured. Epitomies of these cases are given.

10. Bunts, while operating on a huge umbilical hernia in a very obese woman with fatty adherent omentum, accidentally stripped the descending colon of its mesentery for a distance of eight inches. The patient's condition was poor and the cut mesentery was simply sutured to the stripped bowel with interrupted sutures. The patient recovered. This led Bunts to experiment on dogs. In 5 cases the mesentery was separated from the colon for distances of from 3 to 6 inches, and one for a distance of 12 inches. In none was the colic artery proper injured,

and in all the cut mesentery was interruptedly resutured to the bowel. All recovered but the last. In 2 cases the procedure was the same except that the colic artery was ligated. Both died (separation, 4 to 5 and 6 inches). In 3 cases the procedure was the same as at first without resuture of the mesentery to the bowel. All died (separation, 3 to 8 inches). The results are very suggestive.

12. William Mayo reports 120 operations on the rectum for cancer. The mortality during 1908–9 was 9%; prior to that, 16%. Two cases are known to be "alive and well" over nine years after operation, and one over seven years afterward. Inoperable conditions have been due rather to hopeless local extension than to lymphatic metastasis. The mortality is higher in the male, and the percentage of cures smaller, owing to the serious limitation to dissection offered by the bladder, prostate, urethra and vesicles. Sepsis caused the highest percentage of operative mortality. To avoid liquid feces at operation the bowels are cleared out forty-eight hours before operation, as suggested by Hochenegg. Cancers which lie in the lower one and one-fourth inches of the rectum are most satisfactorily dealt with by the Harrison Cripps operation. Cancers of the middle rectum above the levator ani are dealt with by the Quénu-Tuttle operation. In the posterior operations the ventral Trendelenburg position is used, the sacrum is not disturbed, but a parasacral incision is sometimes used. The combined abdominal operation is considered the operation of choice in large majority of cases of cancer of upper rectum and selected cases of cancer of lower rectum. Its mortality in the fleshy male is high. It is not a substitute for the perineal or posterior routes, only a step for more thorough eradication of disease. [T. W. H.]

7. Ross, R., and Thomson, D. *A Case of Sleeping Sickness Showing Regular Periodical Increase of the Parasites Disclosed.*

2. Clarke reports some interesting cases occurring in one family in which hemiplegia with, as a rule, loss of speech was a constant feature of attacks of migraine. As cases of this kind in which the disturbances accompanying migraine are of the motor rather than of the sensory type are rare, he gives the details of his six cases, with remarks on previously reported cases or observations on this phenomenon. He rules out organic disease as a cause of these headaches by the hereditary history of the disorder, the lapse of time during which attacks had taken place without any signs of organic disease, and the fact that in no instance has the recurrent paralysis become permanent. In most of his patients the attacks began in early childhood and were accompanied by headache, characteristic visual phenomena, vomiting, temporary loss of speech and sensory disorders, and motor disorders — in one, paralysis of all four extremities. Between the attacks there was a complete return to normal.

3. Ram discusses the value of serums and vaccines in the treatment of disease. He briefly speaks of the use of vaccines or serums in puerperal septicemia, malignant endocarditis, acute tonsillitis, tetanus, pneumonia, etc. His remarks in regard to the treatment of tuberculosis, especially in regard to the treatment of tuberculous glands, are of interest. "I feel convinced that the extensive dissection of glands of the neck is wrong in principle and sometimes leads to a general tuberculosis which is fatal." In tuberculous peritonitis he believes that tuberculin has a splendid effect as well as in genito-urinary tuberculous disease. [J. B. H.]

1-4. These papers represent a series written on the different methods of treating lupus. They were presented at a meeting, and a discussion by many different men followed. The discussion is also printed in this number.

10. Gutmann, with a series of cases, describes some of the eye conditions which may result from disease of the frontal sinus. He describes two cases of phlegmon of the orbit, one from a perforating frontal sinus empyema, the other from a mucocele of the frontal sinus followed by empyema. He then gives some cases illustrative of the results of operative procedure which resulted favorably. He also describes some cases showing the eye complications from disease of the cribriform plate and ethmoid cells. [C. F., Jr.]

11. Dr. Kayser, after reviewing the history of animal experimentation in the transplantation of the ovary, quotes a case of his own. In operating on a woman thirty-two years old for a left tubo-ovarian tumor, he discovered the right adnexa to be wanting. To prevent premature cessation of menstruation, he transplanted two wedge-shaped portions of the ovary, after removal of the tubo-ovarian mass *in toto*, to the right thigh underneath the vastus externus. The patient made a good recovery and has menstruated with almost perfect regularity since the operation. The patient has also been free from any of the symptoms of premature menopause. The ovarian tissue in the right thigh can be felt, but causes the patient no discomfort. [J. L. H.]

ANNALES DE L'INSTITUT PASTEUR.

MAY 25, 1910.

1. *SERGENT, E., AND FOLEY, H. *Researches upon Relapsing Fever and Its Mode of Transmission in an Algerian Epidemic.*

3. MAZÉ, M. P. *Theoretical and Practical Considerations on the Making of Cheese.*
4. VIALA, J. *Antirabic Statistics of the Pasteur Institute for the Year 1909.*

1. Sergent and Foley worked on an epidemic of relapsing fever in Algiers and came to the following conclusions: Their epidemic was marked by a characteristic set of symptoms and was very free from complications. The prognosis for life was excellent. Judging from the symptoms, this epidemic resembled the European relapsing fever more than the African tick fever.

They describe the spirillum which caused this epidemic and found it inoculable from man to monkey, although it could not be kept going from monkey to monkey. Other inoculations into rats and mice only met with slight success. The spirillum from this epidemic showed itself to be different from that of other epidemics by tests *in vitro* with the serum of immunized animals, and so they called it "Spirochaete berbera."

They experimented with different insects, such as lice, mosquitoes, etc., in order to find the method of transmission. They found positive results only with the lice, and feel that the other insects may be excluded. Whether the lice are the direct cause of transmission is as yet uncertain. [C. F., JR.]

Correspondence.

EXAGGERATION OF THE PREVALENCE OF VENEREAL DISEASE.

ATTLEBORO, MASS., July 18, 1910.

Mr. Editor: I am thoroughly in sympathy with the recent movement to educate the people generally, and especially the rising generation, as to the dangers of venereal diseases. I have been impressed, however, with a tendency in most of this agitation to what seemed to me to be gross exaggeration. For instance, circulars were freely distributed in our town last spring containing the statement that 75% of the adult male population had suffered from gonorrhea. In another paper which recently appeared in the medical journals, it was roughly estimated on the authority of certain specialists that 80% of the male population had been thus afflicted. From my own practice and experience I believe these figures are altogether misleading. My own practice brings me in touch with several hundred men each year from different parts of New England. These are invariably questioned as to the possibility of venereal disease in the past, and only a small proportion of them — not to exceed one third — admit having had trouble of this sort. There is no special reason why these patients should wish to conceal the truth, and the question naturally arises how such statistics are gathered. If patients who are co-operating with their physicians for their own interests will not admit the truth to them, to whom would they admit it? It evidently is misleading to take the opinion of specialists who see nothing but this sort of trouble. Naturally they are willing to attribute these diseases to 80% or 90% of the people who apply to them for treatment.

On the other hand, I am impressed that such statements, if true, would be very unwise in connection with this agitation to young people. They must do more harm than good. Any thinking young man will immediately reflect that if three fourths or more of the business men, professional men and other male members of the community with whom he is acquainted had in their youth had such troubles and not only lived through them, but are able to make a success in life, then there can be but little danger in the trouble. Such statements would only reassure the youth and tend to encourage them in recklessness rather than deter them by any fear of the consequences. I believe, therefore, that such statements are not only greatly exaggerated, but that they are exceedingly unwise.

Very truly yours,

C. C. NICOLA, M.D.

LETTER FROM BERLIN.

THE POLYKLINIK. UNUSUAL CASES OF RETENTION. ISRAEL'S KLINIK. PROSTATIC HYPERTOPHY. NEPHRECTOMY. THE WORKING CAPACITY OF THE OPPOSITE KIDNEY.

BERLIN, June 1, 1910.

Mr. Editor: Probably in no city in the world are there so many and so good opportunities to see clinical work in all branches of medicine as there are in Berlin. This is particularly true of urology. The number of good men here who are really experts in this branch of medical science is quite remarkable. I believe this has been brought about by the system of teaching that prevails here. If a man has ability and energy, he endeavors to become a private teacher so that he may gather around him a number of pupils. To do this he establishes a clinic of his own. This is a simple matter. He hires a few rooms, generally in some congested part of Berlin, where there are many poor, puts out his sign, and patients begin to come to him at once. The German population has come to regard the "*polyklinik*," as it is called, an institution, and it is really a very valuable institution. Patients are well treated, opportunities for study are unrivaled, and lastly, the physician who has started the clinic often rises from this humble beginning to a position of eminence in the medical world.

In these clinics one has occasion to see every kind of case — some among them very rare. One day I saw sitting side by side too very rare cases of retention. The first patient was a man fifty-five years old who had, fifteen years previously, sustained a severe fall, injuring his back. Complete retention followed, lasting many months. Since the accident he has never been able to completely empty his bladder. The diagnosis was hemorrhage of the spinal cord. The second patient was also a middle-aged man who twelve years previously had an operation performed for hydrocele and inguinal hernia. Immediately after the operation there was retention, which was thought to be simply postoperative. But he has never since that time been able to urinate without the catheter. There were no stigmata of hysteria. Both patients had severe cystitis and trabeculated bladder.

If one wishes to see operative work he cannot do better than attend Israel's operative clinic. This is in a large general hospital on Auguststrasse, where operations on the urinary organs take place Mondays, Wednesdays and Saturdays. All are cordially welcome. It is a great pleasure to see Israel operate. Probably no one has had greater experience than he has had, nor greater opportunities. At the head of a large hospital, he commands a vast amount of material. His patients come from all over the world and his reputation is very great, and justly so. Of his operative technic too much cannot be said in praise. It is perfect. He makes no mistakes, operates rapidly, surely and with a finish. Israel makes a long oblique incision for nephrectomy, beginning at the erector spinæ angle and extending well forwards and downwards a little inside of the iliac crest; if additional room is needed, in the case of large tumors of the kidney, he makes a cross incision just under the border of the ribs. The peritoneal cavity is not opened. The light from the window shines directly into the wound, the patient being on his side and slightly raised by means of a small hard pillow not more than six to eight inches in diameter, and, as the operator stands somewhat towards the patient's knees facing the patient's head, which is away from the window, he has complete command of the field. This is the best position for nephrectomy I have ever seen. The space given is considerable, and with efficient retraction of the edges of the wound it is possible to see even well under the ribs. Israel clamps his vessels, removes the kidney and ties the stump with one stout ligature. He does not transfix. If there is a thrombus in the vena cava, as sometimes happens in the case of malignant disease of the kidney, Israel does not hesitate to incise the vein, remove the thrombus and sew up the vein again.

One sees but few prostatectomies in Berlin, and I believe the operation is not much in favor. They seem to prefer the palliative treatment for prostatic hypertrophy.

In the matter of determining the working capacity of the "opposite" kidney the Germans excel. With a careful man it is seldom that a patient dies after nephrectomy from insufficient action of the remaining kidney. Their method is thorough and takes but a short time, about three hours being all that is required. The method is as follows: (1) Be sure that the test is performed in the early morning, preferably before eating and drinking, especially the latter — a very dilute urine will cause the test to fail because the sugar secreted in the phloridzin test may be so slight in amount from dilution as to make the tests unsatisfactory. (2) Both ureters are catheterized and an endeavor made to get the total output of urine from each kidney; unless you do this the cryoscopy test is useless. (3) The urine as it flows from the ureters is collected in test tubes of very small bore; this allows of a relatively small amount of urine being used for testing. (4) The following scheme is now followed: (*a*) General appearance of each urine, its odor, color, transparency; (*b*) albumen test on each side; (*c*) sediments; (*d*) phloridzin test, each side; (*e*) indigo carmine test, each side; (*f*) cryscopy, each side; (*g*) total amount of urine passed each side from the insertion of catheters to time of withdrawal.

The phloridzin test is very easily and rapidly performed with the appropriate apparatus. The precaution is to use a perfectly fresh solution and to warm it before injecting. A 1-100 solution is used, and of this 1 ccm. is injected subcutaneously. Sugar ought to appear in the urine from a healthy kidney in about fifteen minutes. The time of injection is noted, and also the time of appearance in the urine from either kidney. This is ascertained by examining repeatedly small amounts of urine collected in the narrow bored test-tubes; the Nylander bismuth test is employed for this purpose. Fifteen minutes from the time sugar has first appeared on either side the sugar percentage may be tested for. To do this, collect all the urine from each side separately from the time the sugar has been detected on one side or the other; using this urine, do the Lohnstein's fermentation test. The Lohnstein apparatus is a curved glass tube, in the bottom of which is a quantity of mercury. On one side is a graduated scale showing percentages; on the other is a cup into which is placed 1 ccm. of the sugar urine plus a small amount of baker's yeast. A glass stopper is now forced into the neck of the cup and a weight put on top of the stopper to prevent the expanding gas from forcing it out. The whole apparatus is now placed in an oven at a temperature of 37.5° Centigrade and allowed to remain there two hours. At the end of this time fermentation will have been completed and the expanding gas will have forced the column of mercury up the tube, and the percentage of sugar may be read off. This is Caspar's method. Israel prefers to leave the apparatus in the oven twelve hours. The indigo carmine test is simple enough. It should always follow the phloridzin test. The rule is to inject the carmine ten minutes after the phloridzin has been injected. The blue color does not interfere with the sugar test. A simple and easy solution is that made with the Brückner, Lampe & Co. (Voelcker Joseph) tablets of indigo carmine, dissolving one tablet in 10 ccm. of warm sterile water. It makes a clean solution which contains no sediment. The time of injection of the carmine is noted, and likewise the time of its first appearance.

The cryscopy test is best performed with the Beekman apparatus. It is necessary to get the total output from each kidney in a given time in order to have the test of any value.

Israel's summary of the whole question of determination of renal efficiency is about as follows: Testing by means of the various tests is not a mathematical problem. It is by taking the information gained in the gross rather than in detail that an opinion is arrived at; most information is gained by a careful chemical, microscopical and bacteriological examination of the separated urines. Cryoscopy comes next in point of importance if you have the total output of each kidney. Phloridzin and indigo carmine come next. Besides all this, you must consider the general condition of the patient, his disease, his mental and physical makeup, his previous habits, and history. It is largely a question of good judgment, and the well-balanced man accustomed to weigh each case on its own merits will be the one who will make fewest mistakes in advising for or against an operation.

LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND OTHER OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED JULY 13, 1910.

STONER, G. W., surgeon. Granted four days' leave of absence from July 3, 1910, under paragraph 189, Service Regulations.

MAGRUDER, G. M., surgeon. Granted one month's leave of absence from July 8, 1910, on account of sickness.

COBB, J. O., surgeon. Leave for seven days from June 26, 1910, amended to read three days from June 26, 1910.

STIMPSON, W. G., surgeon. Directed to proceed to Tuckerton and Atlantic City, N. J., for the purpose of making examination of keepers and surfmen of the life-saving service. July 11, 1910.

CUMMING, HUGH S., passed assistant surgeon. Directed to proceed to Ocean City, Md., and Chincoteague, Wachapreague, and Cape Charles City, Va., for the purpose of making examination of keepers and surfmen of the life-saving service. July 11, 1910.

LAVINDER, C. H., passed assistant surgeon. Granted three days' leave of absence en route in Europe under paragraph 189, Service Regulations.

VON EZDORF, R. H., passed assistant surgeon. Leave for five days from June 28, 1910, amended to read three days from June 28, 1910, on account of sickness.

FOX, CARROLL, passed assistant surgeon. Granted seven days' leave of absence from July 9, 1910, under paragraph 191, Service Regulations. Directed to proceed to Point Pleasant, N. J., for the purpose of making examination of keepers and surfmen of the life-saving service. July 11, 1910. Granted seven days' leave of absence from July 16, 1910.

MCLAUGHLIN, A. J., passed assistant surgeon. Relieved from duty at Manila, P. I., and directed to proceed to San Francisco, Cal., reporting arrival to Bureau by wire. July 7, 1910.

FOSTER, A. D., passed assistant surgeon. Relieved from duty at Hongkong, China, and directed to proceed to San Francisco, Cal., reporting arrival to Bureau by wire. July 11, 1910.

PORTER, J. Y., quarantine inspector. Directed to make inspections of certain quarantine stations of Florida from time to time during present season. July 7, 1910.

BREADY, JOHN E., acting assistant surgeon. Granted twenty-seven days' extension of annual leave from June 2, 1910, on account of sickness.

CONVERSE, GEO. M., acting assistant surgeon. Granted seven days' leave of absence from July 11, 1910, under paragraph 210, Service Regulations.

CREPIN, H. E., acting assistant surgeon. Granted seventeen days' leave of absence from July 5, 1910.

FALK, C. C., acting assistant surgeon. Granted ten days' leave of absence from July 8, 1910.

HORNING, HENRY, acting assistant surgeon. Granted seven days' leave of absence from July 6, 1910, under paragraph 210, Service Regulations.

MASON, WM. C., acting assistant surgeon. Granted nine days' leave of absence from June 23, 1910.

SCHUG, F. J., acting assistant surgeon. Granted fifteen days' leave of absence from July 9, 1910.

STUART, ALBERT F., acting assistant surgeon. Granted thirty days' leave of absence from July 5, 1910.

LAGRANGE, J. V., pharmacist. Granted seven days' leave of absence from July 9, 1910, under paragraph 210, Service Regulations.

ILTIS, G. W., pharmacist. Granted seven days' leave of absence from July 1, 1910, under paragraph 210, Service Regulations.

STIER, CARL, pharmacist. Granted one day's leave of absence, June 16, 1910, under paragraph 210, Service Regulations.

BIERMAN, C. H., pharmacist. Granted ten days' leave of absence en route to station.

STERNS, C. O., pharmacist. Granted one day's leave of absence in June, 1910, under paragraph 210, Service Regulations.

ELDREDGE, M. B., pharmacist. Granted three days' leave of absence from July 5, 1910, under paragraph 210, Service Regulations.

APPOINTMENT.

CLAUDE C. CANNON appointed a pharmacist of the third class. July 6, 1910.

CHANGES IN THE MEDICAL CORPS U. S. NAVY DURING THE WEEK ENDING JULY 23, 1910.

REED, E. U., passed assistant surgeon. Detached from duty from Naval Hospital, Norfolk, Va., and ordered to duty on the U. S. S. "Philadelphia." July 16.

DIEHL, O., medical inspector. Detached as fleet surgeon, U. S. S. "Charleston," Asiatic fleet, and ordered home. July 21.

JOHNS HOPKINS HOSPITAL AUG 9 1910 LIBRARY

DANVERS STATE HOSPITAL LABORATORY PAPERS, 1910,

Charles Whitney Page Series.

I. THE LABORATORY WORK OF THE DANVERS STATE HOSPITAL, HATHORNE, MASSACHUSETTS WITH ESPECIAL RELATION TO THE POLICY FORMULATED BY DR. CHARLES WHITNEY PAGE, SUPERINTENDENT, 1888–1898, 1903–1910.

BY E. E. SOUTHARD, M.D.

Bullard Professor of Neuropathology; Harvard Medical School; Pathologist to the Board of Insanity, Massachusetts.

II. THE MARGIN OF ERROR IN THE DIAGNOSIS OF MENTAL DISEASE: BASED ON A CLINICAL AND ANATOMICAL REVIEW OF 250 CASES EXAMINED AT THE DANVERS STATE HOSPITAL, MASSACHUSETTS, 1904–8.

BY E. E. SOUTHARD, M.D.

III. A STUDY OF THE DEMENTIA PRECOX GROUP IN THE LIGHT OF CERTAIN CASES SHOWING ANOMALIES OR SCLEROSES IN PARTICULAR BRAIN REGIONS.

BY E. E. SOUTHARD, M.D.

IV. TEN OBSCURE CASES OF MENTAL DISEASE: A CLINICAL AND ANATOMICAL STUDY.

BY L. B. ALFORD, A.B.,

Laboratory Interne, 1910, Danvers State Hospital.

V. A STUDY OF THE SENILE SPINAL CORD IN CASES OF MENTAL DISEASE.

BY A. S. HAMILTON, M.D.,

Instructor in Neuropathology, University of Minnesota; Student, Harvard Summer School of Medicine, 1909; Laboratory Interne, 1909, Danvers State Hospital.

VI. A HISTOLOGICAL STUDY OF THE THYROID GLAND IN MENTAL DISEASE, WITH SPECIAL REFERENCE TO CHRONIC THYROIDITIS.

BY A. H. PEABODY, M.D.,

Assistant Physician at the Danvers State Hospital.

VII. INCIDENCE OF HEART DISEASE IN ACUTE PSYCHOSES, DANVERS STATE HOSPITAL, MASSACHUSETTS, 1879–1909.

BY ALBERT A. HORNOR, 2D, A.B.,

Student, Harvard Medical School; Laboratory Interne, 1909, Danvers State Hospital.

VIII. BACTERIAL INVASION OF THE BLOOD AND THE CEREBROSPINAL FLUID BY WAY OF MESENTERIC LYMPH LODES: A STUDY OF FIFTY CASES OF MENTAL DISEASE.

BY E. E. SOUTHARD, M.D., AND MYRTELLE M. CANAVAN, M.D.

Assistant Pathologist to the Danvers State Hospital.

IX. BACILLARY DYSENTERY AT THE DANVERS STATE HOSPITAL, MASSACHUSETTS, SUBSEQUENT TO THE EPIDEMIC OF 1908 (DECEMBER, 1908–JUNE, 1910).

BY MYRTELLE M. CANAVAN, M.D.

X. ORGANISMS RECOVERED FROM DYSENTERY CASES STUDIED BACTERIOLOGICALLY, DECEMBER, 1908–JUNE, 1910, DANVERS STATE HOSPITAL, MASSACHUSETTS.

BY MYRTELLE M. CANAVAN, M.D.

XI. THE PERSISTENCE OF AGGLUTININS FOR B. DYSENTERIÆ IN DANVERS HOSPITAL CASES, TOGETHER WITH A SERIES OF CONGLUTINATION TESTS.

BY MYRTELLE M. CANAVAN, M.D.

XII. MANNITE- AND NON-MANNITE-FERMENTING ORGANISMS IN A CASE OF DYSENTERY, COMPLICATED BY HEMORRHAGIC ENDOMETRITIS PROBABLY DUE TO A THIRD ORGANISM.

BY MYRTELLE M. CANAVAN, M.D.

XIII. PRIMARY ADRENAL TUBERCULOSIS IN A CASE OF JUVENILE GENERAL PARESIS WITH MENINGEAL INFECTION (BACILLUS COLI COMMUNIS).

BY E. T. F. RICHARDS, M.D.,

Assistant Physician, State Infirmary, Tewksbury, Mass.; Assistant in Neuropathology, Harvard Medical School; formerly Laboratory Interne at Danvers State Hospital. (Proctor Foundation for the Study of Chronic Disease.)

XIV. A CASE OF AUTOCHTHONOUS SINUS-THROMBOSIS.

BY F. ROBERTSON SIMS, M.D.,

Assistant in Neuropathology, Harvard Medical School; formerly Assistant Physician, Danvers State Hospital.

XV. THE DIAGNOSIS OF FRACTURED SKULL AS AIDED BY THE FINDING OF BRAIN TISSUE IN THE VOMITUS.

BY GORDON T. BROWN, M.D., BRANT, ALBERTA,

Formerly Assistant Physician at Danvers State Hospital.

XVI. NOTE CONCERNING BRAIN AND OTHER VISCERAL WEIGHTS IN SIXTY-SIX SUBJECTS SHOWING CARCINOMA OR SARCOMA.

BY NEWELL B. BURNS, M.D.,

Laboratory Interne, 1909, Danvers State Hospital.

XVII. SOME EFFECTS OF OVERFEEDING WITH FATS IN CERTAIN CASES OF INSANITY.

BY HERMAN M. ADLER.

I.

THE LABORATORY WORK OF THE DANVERS STATE HOSPITAL, HATHORNE, MASSACHUSETTS, WITH ESPECIAL RELATION TO THE POLICY FORMULATED BY DR. CHARLES WHITNEY PAGE, SUPERINTENDENT, 1888–1898, 1903–1910.

BY E. E. SOUTHARD, M.D.

THE papers here collected represent the work, hitherto unpublished, of the last year or more in the Danvers State Hospital laboratory. At the time of Dr. Page's sudden and unexpected decision, in the spring of 1910, to retire from the superintendency of the Danvers Hospital, the laboratory workers in the hospital cast about forthwith for a way to express publicly their gratitude for his ardent support, and these papers — the product of their current work — have been here collected as the best token of honor at their command.

Those who know the difficulties of psychiatric work in general, and the almost universal lack of interest in psychiatry exhibited by the American practitioner of medicine, must be aware how little incentive to the hospital superintendent there is to wander afield from the circle of purely administrative and financial praise. To be a measurably good administrator and manager is becoming increasingly difficult. The state hospital superintendent is fast becoming a strategist, and no longer purely a tactician, and with the added hardship that many boards of trustees require him to be both. The administrative strategist of our state hospitals is in no position to cultivate the science of medicine; he is, in fact, losing immediate touch with the art of medicine. If he spends his time knowing his patients all by name and face, he must in many instances content himself with being a captain rather than a general. But generalship is what the modern state hospital demands of its superintendent.

Yet the military system of running great hospitals has its drawbacks. The fight we are trying to win or draw is, after all, not merely a financial fight, but a humanitarian fight. The patient, not the cost *per capita*, is the object of medical interest, which is itself only a concentration and refining of the interest of the public at large. The *per capita* considerations emerge soon enough. Nothing so quickly terminates humanitarian effort as extravagance and irregular or illogical expenditure.

In no wise supported by the American medical profession, which is, as a body, grossly ignorant of mental disease, and in his procedure dominated by considerations of *per capita* cost, as emphasized by governing boards, what wonder that the hospital superintendent often relapses into a martyred feeling of doing the best he can under the circumstances. The young man who preaches the value of science is apt to be termed a misguided enthusiast with inapplicable, not to say wholly millennial, ideas.

What happens to science in this plight? The neighboring university or medical school usually presents some enthusiastic young person with ideas drawn from pure biology, whether morphological, physiological or psychological, and this man is appointed pathologist. The pathologist now pursues, under cover of supervising or performing urine and blood analyses and autopsies,— *psychiatric problems?* No; the *biological problems*, which his university training permits him to make the most of. The pathologist may then relapse into a pure routinist; he may get interest in clinical problems and turn into a consultant or even into a superintendent; he may succeed so well in his biological work as to acquire important university connections and secede from psychiatry utterly, and for many of our young men the problem is not yet solved.

It is, therefore, not surprising that the pathologist to a state insane hospital has become understood to be a man pursuing the highest type of biological research of which he is capable under the aegis of the state. The model of certain privately endowed institutions has here been followed. Science is slipped in where legislators and trustees will not be concerned by it. The attitude of many superintendents to the introduction of science into their institutions is little short of refined smuggling. Of two equally high-minded superintendents, the one smuggles science in for the cause, the other regards this process as unethical and spends his energy on the creature comforts of his charges.

This situation seems to be chiefly due to a misconception of the possibilities of hospital laboratories. They have come to be regarded as addenda for pure research (whatever that may really mean!) and not as instruments of direct clinical value. *Clinical laboratories*, rather than research laboratories, are proper and, indeed, indispensable parts of a modern state insane hospital. *Research laboratories* belong, in the first instance, to universities and to privately endowed institutions. After demonstration of the value of clinical laboratories (and research products invariably accrue from good clinical laboratories), the state may become willing to invest in research laboratories. Shipwreck awaits reversal of this natural development. The research laboratory, set down complete and self-contained in a state hospital, is very apt to languish. Instances of such languishment or utter disappearance of exotic research laboratories could readily be multiplied in America.

But let the problems arise in the patients, and the clinico-pathological aim be held in mind, let the science be *applied* science, and the arrangement is never short-lived, nor does the laboratory become sequestered or subject to atrophy.

These peculiar conditions warrant our taking note of all such special and differentiated efforts as those of DR. CHARLES WHITNEY PAGE to develop a laboratory in a state hospital for the insane along durable lines. Doubtless we shall never pass through a similar era of transition again, and, when state hospital laboratories have become universally regarded as necessities, not luxuries, as local immediate benefits to the patient, not as hostages to the fortune of patients a century hence, we can afford to smile retrospectively at the hesi-

tant inductive progress of the early Danvers work. Already from the Government Hospital for the Insane in Washington, Superintendent White is preaching the advanced doctrine that the patient is benefited, and directly benefited, by the execution of pure research within the hospital walls: the most concrete benefit is to the stimulated staff. New York state and Michigan have central institutions of a type which prove that central authorities believe that *investigation pays*, and conversation with institutional officers from these states proves the general appreciation of these efforts, not merely in their research aspect, but also as to the direct educational value of the central institutions to the state officers.

Although no doubt can possibly exist of the extraordinary value of central psychiatric institutions, questions still arise concerning the degree to which local institutions should develop laboratories. The Government Hospital for the Insane at Washington is wholly exceptional on account of its central position. How far shall single state hospitals go? The Danvers State Hospital of Massachusetts presents one pronounced answer to this question.

The Danvers laboratory is, I believe, unique among insane hospital laboratories in having had four pathologists successively in charge whose work exhibits a certain continuity as well as a pronounced differentiation, and even a certain progressive evolution of an inductive sort. This fact argues for a certain durability of the plan as well as for its serviceability. The hospital itself is not especially favored by proximity to a medical center, and, in fact, has not to any extent ever been exploited for teaching purposes by pathologists eager for "material" and — not at all interested in the patients. In fact, Danvers is almost as inconvenient for teaching purposes as is any other state hospital, at least on the Atlantic seaboard.

The first autopsies (in 1879 and subsequent years) were performed, curiously enough by a classmate of Dr. Page, Dr. James Jackson Putnam, now Professor of Diseases of the Nervous System in the Harvard Medical School.

The standards were maintained by later workers, among whom may be mentioned Dr. Henry Rust Stedman, now trustee of the Taunton State Hospital, and superintendent of Bournewood Private Hospital, Brookline, Mass., and Dr. Sanger Brown, attending physician to Cook County, St. Luke's, and St. Elizabeth's hospitals, Chicago, Ill.

Next came an era in which the autopsies are in the main unsigned, and no regular pathologist was appointed until 1895, when, at Dr. Page's instance, the late Dr. William Leonard Worcester was obtained from Little Rock, Ark., as pathologist. The clinico-pathological range of Dr. Worcester's interest is seen from the following list of his papers.

TITLES OF PAPERS WRITTEN BY WILLIAM LEONARD WORCESTER, M.D., BEFORE HIS DANVERS APPOINTMENT.

Diphtheria in the Michigan Asylum for the Insane at Kalamazoo. Rep. Bd. Health Mich., vol. x, 344, 1881–2.

Cases Illustrative of the Localization of Cerebral Functions. Am. Jour. Insan., vol. xliv, 66, 1887.

The Mortality of Epilepsy. Med. Rec., N. Y., vol. xxxiii, 467, 1888.

Four Cases of Pernicious Anemia. N. Y. Med. Jour., vol. xlviii, 491, 1888.

Delirium. Am. Jour. Insan., vol. xlvi, 22, 1889.

Cases of Infantile Hemiplegia. Jour. Am. Med. Asso., vol. xiii, 302, 1889.

Is Puerperal Insanity a Distinct Clinical Form? Am. Jour. Insan., vol. xlvii, 52, 1890.

Insanity in Twins. *Ibid.*, 535, 1890–1.

Mechanical Restraint in the Treatment of the Insane. *Ibid.*, vol. xlviii, 476, 1891–2.

The Treatment of Ulcers. Jour. Med. Soc. Ark., vol. ii, 438, 1891–2.

The Mortality of Epilepsy in Asylums for the Insane. Jour. Nerv. and Ment. Dis., vol. xix, 177, 1892.

Cases of Multiple Neuritis. Am. Jour. Insan., vol. xlix, 591, 1892.

The Organization of Hospitals for the Insane. *Ibid.*, vol. li, 584, 1894.

Confusional Insanity. Maryland Med. Jour., vol. xxxii, 353, 1894–5. Also: Am. Jour. Insan., vol. li, 71, 1894–5.

TITLES OF PAPERS WRITTEN BY WILLIAM LEONARD WORCESTER, M.D., AFTER HIS DANVERS APPOINTMENT.

What is Insanity? Am. Jour. Insan., vol. lii, 602, 1896.

A Case of Paretic Dementia of Long Duration. *Ibid.*, vol. liii, 319, 1895–6.

A Case of Acromegaly with Autopsy. Boston Med. and Surg. Jour., vol. cxxxiv, 413, 1896.

Sclerosis of the Cornu Ammonis in Epilepsy. Jour. Nerv. and Ment. Dis., vol. xxiv, 229 and 263, 1896.

Cases of Paraphasia and Word Deafness. Am. Jour. Insan., vol. liii, 262, 1896–7.

The Preservation of Serial Sections. *Ibid.*, 287, 1896–7.

The Psychology of Insane Delusions. Trans. Am. Med.-Psychol. Ass., vol. iv, 200, 1897.

A Case of Landry's Paralysis. Jour. Ment. and Nerv. Dis., vol. xxv, 299, 1897.

Some Difficulties in the Retraction Theory. Am. Jour. Insan., vol. lvi, 101, 1897.

Regeneration of Nerve Fibers in the Central Nervous System. Jour. Exp. Med., N. Y., vol. iii, 579, 1898.

The Relations of Renal Disease to Mental Derangement. Trans. Am. Med.-Psychol. Ass., vol. vi, 210, 1899. Also: Am. Jour. Insan., vol. lvi, 275, 1899.

The Katatonic Symptom-Complex. Am. Jour. Insan., vol. lv, 659, 1898.

Three Cases of General Paralysis in Young Women. *Ibid.*, vol. lvii, 127, 1900.

Case of Patent Foramen Ovale in Advanced Age. Boston Med. and Surg. Jour., October, 1900.

In the same year, 1895, Dr. Adolf Meyer had been appointed pathologist to the Worcester State Hospital, coming from the Eastern Hospital at Kankakee, Ill., where he had been pathologist, 1893–1895. Such appointments were, as a matter of fact, in the air, though often determined purely on the score of availability of men. Even to this day hospitals are often unable to procure pathologists when they desire them.

During Dr. Page's temporary stay at the Connecticut Hospital for the Insane at Middletown, he procured the appointment of Dr. A. R. Diefendorf as pathologist, 1898 — Dr. Diefendorf had been assistant physician at the Worcester State Hospital, 1896–1898. During this period the work also of Dr. Jessie Weston Fisher was started at Middletown along bacteriological and hygienic lines.

During Dr. Page's stay at Middletown, Dr. Worcester died at the Danvers Hospital, and Dr. Albert Moore Barrett, who had been

pathologist at Independence, Ia., and had worked for a time with Meyer at Worcester and with Dr. Joseph Fraenkel, of New York, was appointed, after warm advocacy by Dr. Page, during the administration of Danvers Hospital by Dr. A. H. Harrington. Dr. Barrett spent a year in Germany, for the most part with Nissl and Kraepelin at Heidelberg, after receiving his Danvers appointment, and greatly influenced the writer, who was at that time, in an interval in his Boston City Hospital laboratory appointments, preparing to develop a course in neuropathology at the Harvard Medical School.

During his Danvers service, Dr. Barrett was particularly interested in developing the clinical diagnosis of mental disease and in correlating these conditions with the histology of the cerebral cortex, and various studies from Barrett's cortex collection, which has been continued, have since been made and will hereafter be made. Barrett has published the following papers from Danvers material:

Disseminated Syphilitic Encephalitis. Am. Jour. Med. Sc., March, 1905.

A Study of Mental Diseases Associated with Cerebral Arteriosclerosis. Am. Jour. Insan., vol. lxii, 1, 1905.

Spinal Cord Degenerations in a Case of Acromegaly, with Tumor of the Pituitary Region. Am. Jour. Med. Sc., February, 1906.

With H. W. Mitchell: Posterior Column Degenerations Following Injury to the Posterior Roots of the Seventh Cervical Nerves. Jour. Nerv. and Ment. Dis., vol. xxxv, 1908.

A Case of Pure Word-Deafness with Autopsy. *Ibid.*, vol. xxxvii, 1910.

Dr. Louis Hoag was assigned to laboratory duty in Dr. Barrett's service and spent much time in bacteriological work, most of which has not been published. He was especially interested in a diphtheroid organism, a preliminary report of which has been published.

"Organism X," Probably of the Corynebacterium Group: Its Differentiation from B. Diphtheriæ and Allied Organisms; Its Pathogenicity in Man, Especially in Bronchopneumonia, and Its Relation to General Paralysis of the Insane. Boston Med. and Surg. Jour., 1907, 157.

Although Dr. Hoag's work remains largely unpublished, its general results were of value in the laboratory in teaching the probable meaning of Ford Robertson's results in Scotland; for, in intensively following up diphtheroid organisms, the laboratory had come to be aware in how many non-paretic cases these organisms occurred.

Dr. Barrett was appointed assistant in neuropathology at the Harvard Medical School for the year 1905–6 and gave the first series of ward demonstrations to the second-year class in December, 1905. He was then appointed director of the psychopathic ward and professor of psychiatry in the University of Michigan, beginning Jan. 1, 1906.

The writer was appointed pathologist to take Dr. Barrett's place Jan. 1, 1906. Dr. Frederick Parker Gay was appointed bacteriologist to the hospital in August, 1906, and retained his connection one year, leaving to pursue research in immunology as assistant in pathology at the Harvard Medical School. Dr. Gay retained an advisory position with respect to the hospital, which will only be terminated by his approaching assumption of the professorship of pathology at the University of California.

Dr. Anna H. Peabody had been placed on the laboratory staff late in 1905, and Dr. Myrtelle Moore Canavan was appointed in the summer of 1907. Both have pursued histological and bacteriological studies, in part published.

Dr. E. T. F. Richards, working under the Proctor Foundation for the Study of Chronic Disease, was maintained by the hospital to continue the bacteriological work systematized by Dr. Gay. An opportunity for close correlation with the ward staff occurred in the extensive dysentery epidemic at Danvers Hospital in 1908. In the epidemiological side, a special laboratory interne, Mr. C. T. Ryder, a student at the Harvard Medical School, performed a thorough piece of work.

The whole was published as a special report in the Boston Medical and Surgical Journal in November, 1909.

REPORT OF AN EPIDEMIC OF BACILLARY DYSENTERY.

I. Statistical Report of the Dysentery Epidemic at Danvers Hospital in 1908. C. T. Ryder.

II. Investigation of the Possible and Probable Sources of Infection and of the Causes of Spread of Dysentery in Danvers Hospital. C. T. Ryder.

III. Identification of Epidemic Dysentery in Danvers Hospital as due mainly to Bacillus Dysenteriæ (Shiga Type). E. T. F. Richards, A. H. Peabody and M. M. Canavan.

During 1907 Dr. James Bourne Ayer, Jr., served for a time as assistant pathologist. His papers, except those with Gay, are as follows:

Cyst of Dura Mater Occupying the Left Middle Cranial Fossa Associated with Anomalous Development of the Left Superior Temporal Gyrus. Am. Jour. Insan., lxiv, 3, 1908.

With E. E. Southard: Dementia Precox, Paranoid, Associated with Bronchiectatic Lung Disease and Terminated by Brain Abscesses (Micrococcus Catarrhalis). Boston Med. and Surg. Jour., 1908, 159.

With H. A. Cotton: The Cytological Study of the Cerebrospinal Fluid by Alzheimer's Method, and Its Diagnostic Value in Psychiatry. Rev. Neurol. Psychiat., 1908, 6.

Although Dr. H. A. Cotton was never, technically speaking, on the laboratory staff, his connection was actually so close, before his departure as director of the Trenton Insane Hospital, New Jersey, that he may be almost claimed as a laboratory man. His paper with Ayer has been mentioned above. Another was the following with the writer:

A Case of Central Neuritis with Autopsy. Am. Jour. Insan.

The writer was appointed pathologist to the State Board of Insanity, Massachusetts, in May, 1909, and his papers, except those mentioned above, are as follows:

PAPERS BY E. E. SOUTHARD.

At this time, since the anatomical, histological and bacteriological methods had been established, the chemical, or, more properly, the clinico-chemical, point of view became appropriate, and Dr. Page's last appointment of a pathologist was that of Dr. Herman M. Adler. Dr. Adler represents the point of view of clinical research and has assumed charge of certain chosen patients, from whom the most can be learned, so far as can be predicted, from the clinical laboratory methods of internal medicine.

It seems obvious that the Danvers Hospital has enjoyed unusual advantages in many ways, but especially in the dominant policy of its retiring superintendent.

Dr. Page's institution of daily clinics is mentioned in Article II of this series ("The Margin of Error in the Diagnosis of Mental Disease"), where also are reprinted the conclusions of the writer's papers on "Errors in the Diagnosis of General Paresis" and "Anatomical Findings in Senile Dementia," both of which studies are wholly dependent on this system of daily clinics. The following is taken from the writer's discussion (with minor errors corrected) of Dr. Elbert M. Somers' paper before the American Medico-Psychological Association at Atlantic City in 1909, on "The Value of Staff Conferences in State Hospitals."

Dr. Southard. — "I would like to say a word about the economy of this conference system, because lately I have been enjoying the fruits of the daily staff conference at Danvers Hospital in a review of autopsy findings in cases that have been through the daily clinics. I wrote to Dr. Cowles, formerly of McLean

Hospital, to learn whether he had any data relating to the time at which this system was adopted, and he has written me a letter concerning the development attained at the McLean Hospital. He assigned the origin of such conferences originally to Germany, to Professor Ranke, who held a seminar for the discussion of historical matters by his pupils. That system has, of course, now spread into a number of our universities.

"In 1889, if I remember the date, the conferences were introduced at McLean. These conferences largely had the aspect of meetings at which special topics were considered and occasionally an introduction of patients. And then came in a number of hospitals in Massachusetts and elsewhere the occasional conference, perhaps a weekly conference.

"Dr. Page introduced the daily clinic in Middletown, Conn., during the latter years of the last decade of the nineteenth century, and, if I remember aright, it was in 1899. At the Danvers Hospital, in Massachusetts, it was begun and accurately recorded in 1903. We now have complete records for five years there. During that time a large number of cases have gone through the clinic, and 247 of them have come to autopsy. I have been reporting this year some data concerning the accuracy of diagnosis of certain diseases which I think bear upon medico-legal and other questions. At the New York meeting of the American Neurological Association, I showed that, on the basis of diagnosis in these clinics, the probable accuracy of diagnosis in the disease general paresis was 85%, or, if cases of tabes complicating mental disease were excluded, since these would perhaps not be termed errors of diagnosis, then the probable error of diagnosis was 1 in 10.

"The importance of these particular determinations of diagnostic accuracy lies in the fact that the diagnoses were made by several men. There was no induced uniformity of diagnosis due to autocratic methods, which must be in vogue in a certain degree in psychiatric institutions in the old world, but in our institutions we have the advantage of controversies among the assistant physicians. The Danvers daily clinics are very likely to bring out disagreements. Several members of this Association have been at times on the staff, and they are not all tempted to agree if there is any chance to disagree on the diagnosis.

"This shows that the development of the daily clinics has turned from the autocratic German, or one-man system, over to the republican system of considering diagnoses. That goes hand in hand with the method introduced (by Dr. Page) of giving cases in rotation to the different members of the staff so that even the younger members of the staff shall take the responsibility of diagnosis. I will venture to say, basing my ideas upon these results, that it is probably better so to introduce a feeling of responsibility in the younger men than to gain a somewhat greater accuracy of observation by leaving all the cases in the hands of some clinical director, first assistant or other possibly autocratic person.

"The exact recording of these diagnoses at a time long *prior to the making up of the annual report*, and without specific relation thereto, is important, and the fact that the diagnosis is set down in this way *before the autopsy* is another feature which makes results of importance in comparison with the results in an outpatient clinic.

"I said that the accuracy of diagnosis in general paresis was 9 out of 10; that is to say, out of 10 cases in which medical persons, or at least medical men of the average Danvers type, made the diagnosis, there would be 1 of the 10 which would not turn out at autopsy to be a case of general paresis.

"When we come to senile dementia, as I hope to show later in this session, the successes in diagnosis were 7 out of 10, at least taking the criteria of the books. I believe that by this correlating of autopsy findings with these republican diagnoses by the various members of the staff, we shall be able to improve our diagnostic ability."

Closely following in interest upon the daily clinic is another achievement of Dr. Page — the remarkable *index of symptoms* shown by all the patients at Danvers Hospital since its foundation in 1879. This gigantic task is now complete and the data so collected that, with very little labor, the index can be continued in future. Of course, the early observations leave much to be desired, but the data are in the main reliable so far as they are positive. For the more recent years they are of extreme service, as several pieces of statistical work now in progress have shown.

In this review I have not entered at all upon the individual aspects of Dr. Page's service, as, e. g., upon his early and constant advocacy of the non-restraint policy. His papers are as follows:

PAPERS WRITTEN BY CHARLES WHITNEY PAGE.

How can we Escape Insanity? Rep. State Bd. Health Connecticut, 1882.

The Relation of Attention to Hypnotic Phenomena. Am. Jour. Insan., July, 1890.

The Adverse Consequences of Repression. *Ibid.*, January, 1893.

Paranoid Dementia. Am. Jour. Insan., vol. lx, no. 3, 1904.

Mechanical Restraint and Seclusion of Insane Persons. BOSTON MED. AND SURG. JOUR., vol. cli, 22, 1904.

Tuberculosis in the State Institutions for the Insane. In Report of State Commission for Tuberculosis, Massachusetts, 1908.

Dr. Charles Whitney Page was born in 1845 and graduated at the Harvard Medical School in the class of 1870.

It is interesting that in his medical class and in neighboring classes graduated several other men who have since enriched the public medical service of Massachusetts. In Dr. Page's own class of 1870 graduated DR. CHARLES FOLLEN FOLSOM, for many years secretary of the Massachusetts Board of Health, a member of the commission which established the desirability of the Massachusetts Board of Insanity, and always a great force in the community for the improvement of psychiatric conditions, as well as DR. JAMES JACKSON PUTNAM, who, as noted above, was later to become pathologist to the Danvers Hospital. In the class below Dr. Page's graduated DR. GEORGE BRUNE SHATTUCK, for many years consulting physician at the Danvers Hospital. DR. GEORGE FREDERICK JELLY, long a member of the Massachusetts Board of Insanity, and DR. HOSEA MASON QUINBY, superintendent of the Worcester State Hospital, graduated in the class of 1868. Also in attendance at the medical school during Dr. Page's time were DR. WALTER CHANNING (1872), now

chairman of the Board of Trustees of the Boston State Hospital, and the late Dr. James Bourne Ayer (1873), a former member of the Massachusetts Board of Insanity.

Other physicians who attended the Harvard Medical School during Dr. Page's years and have since become of public note, although not identified with work in insanity, were William Lambert Richardson (1867); Henry Pickering Bowditch (1868), George Washington Gay (1868), John Hildreth McCollom (1869), James Read Chadwick (1871), George Howard Malcom Rowe (1868), Reginald Heber Fitz (1868), Frank Winthrop Draper (1869) and William James (1869).

Dr. Page served at the Hartford Retreat for the Insane, as assistant physician, from 1874 until 1888. He was elected superintendent of Danvers Hospital in June, 1888, and resigned in August, 1898, to become superintendent of the Connecticut Hospital for the Insane, Middletown, Conn. He resigned the latter position in September, 1901, and returned to the Danvers Hospital as superintendent in March, 1903. His resignation as superintendent of the Danvers Hospital was handed to the trustees in March, 1910, to take effect July 1, 1910.

The absolutely indispensable aid of the Board of Trustees must never be forgotten in estimating the work of an institution like the Danvers Hospital and of its superintendent.

The trustees of the Danvers Hospital spread upon their records at the time of Dr. Page's resignation the following, —

"The Trustees, having very reluctantly accepted Dr. Page's resignation as superintendent of the hospital, desire to place upon the records a statement of their appreciation of his services.

"He has served the state for many years and has shown unusual executive ability, judgment, force and initiative.

"He abolished mechanical restraint in the institution at a time when its use was general in this country; he was one of the first to establish a pathological laboratory in a hospital for the insane, which laboratory, judged by the amount and character of the work done, is second to none in this country; he was responsible for the building of the congregate dining room, which has promoted economy and the well-being of the patients. The hydrotherapeutic baths established by Dr. Page have met our highest expectations and will long remain a monument to his zeal in the use of physiological therapeutics.

"He took the initiative in erecting two tuberculosis wards, thus setting the example for other hospitals for the insane in this state.

"Under his administration there has been held a daily psychiatric clinic which has been not only of direct benefit to the patients, but has been a valuable source of instruction in psychiatry to the medical staff.

"Owing to this daily instruction, and to Dr. Page's unceasing efforts to obtain the best men available, the medical staff of the hospital has been second to none in the state.

"The largest part of Dr. Page's life work has been done in this hospital. It is a work that reflects the highest credit upon him and that makes this board, the hospital and its patients and the commonwealth his debtors."

What has been brought out *in extenso* above refers to the more purely scientific side of the Danvers work, as largely favored, advocated and mechanized by Dr. Page, to whom we wish to present the product of our recent work in the articles of this series. The chief considerations are as follows:

1. The insane hospital gets no vital support from a medical profession ill-educated in mental disease.

2. The situation is apt, in America at large, to be dominated by the *per capita cost* rather than by the humanitarian considerations which underlie the whole system of treatment of the insane.

3. The superintendency of a state hospital for the insane has become a position requiring generalship; is strategic rather than tactical.

4. Since the superintendent has oversight of the science as well as the art of psychiatry, as exemplified in his hospital, it becomes his duty continually to improve the laboratory as well as the ward facilities, and this *in the interest of the patient*.

5. Dr. Page's Danvers work has contributed to the economics underlying the proper co-ordination of the two aspects — the ward and laboratory aspects — of the large problem of diagnosis and treatment of insane patients in state hospitals.

6. Special attention may be drawn, (*a*) to the appointment of specially (though very variously) trained men to the pathologistships; (*b*) to the encouragement by maintenance of special laboratory internes; (*c*) to the daily clinic system with its republican feature of rotating leaders; and (*d*) to the complete index of symptoms now on file for all Danvers patients.

7. The maintenance of clinico-pathological laboratories in state hospitals for the insane is argued as a method for general adoption on account of improvements in diagnosis, and hence in treatment, which follow their establishment.

II.

The Margin of Error in the Diagnosis of Mental Disease: Based on a Clinical and Anatomical Review of 250 Cases Examined at the Danvers State Hospital, Massachusetts, 1904–8.*

BY E. E. SOUTHARD, M.D.

(From the Laboratory of the Danvers State Hospital, Hathorne, Mass.)

With the broadening of modern duties to the insane, nothing is more patent than the increasing necessity of accurate diagnosis. *Insanity* (a legal conception) has been supplanted by *the insanities* (a medical conception). And *the insanities* now grow, divide, multiply and die in the periodical literature quite after the fashion of disease entities in general. But the necessity of knowing which of the insanities a man has is no longer dictated by curiosity.

The diagnosis of mental disease actually modifies treatment. Institutional or home treatment,

* Read at the Washington meeting of the American Neurological Association, May, 1910.

hospital or asylum treatment, family care, special diets, drugs, baths or social service all are chosen on the basis of one's conception where the patient belongs nosologically. Especially is this true of the subtle modern forms of individualized treatment, whose applicability is so sharply limited to certain classes of patients.

From the standpoint of helping the individual patient and husbanding the state's resources, nothing can be wiser than to exert every effort to classify our patients better. We can rarely look to the general practitioner for a diagnosis, since medical-school instruction in psychiatry has been and still is inadequate. The patients arrive at the institution for the insane, as a rule, quite innocent of any adequate diagnosis.

This duty falls to the lot of the assistant physician, whose erroneous diagnoses (as well as some of his correct ones) are altered by the superintendent (or his deputy) for the official purposes of an annual report. As one well-known alienist has remarked, "The superintendent tires of the discussion and determines the matter."

The old order is changing, however, and an essential democracy is observable in many insane-hospital staffs. I will not say that in Massachusetts we constitutionally disagree. But, as the hospital superintendency has there become a strategic rather than a tactical position, the subordinate medical officers have assumed a greater dignity and independence, with tremendous benefit to the whole situation. The superintendent no longer thinks of "determining the matter," leaving that to the recorded facts or even leaving the matter undetermined.

A specially democratic plan has prevailed at the Danvers State Hospital, Massachusetts, which has the advantage that records have been preserved of the opinions of several diagnosticians (from three to eight, as a rule) concerning patients long before discharge, demise or other determination of the diagnosis has taken place. *Intra-vitam* diagnoses by the physicians in charge and by their more or less critical colleagues have thus been recorded for all but a small minority of the patients admitted to the Danvers State Hospital since 1904. This system, due to the superintendent, Dr. C. W. Page, will be described more in detail elsewhere. Its results are salutary in all ways.

A peculiar result of the Danvers system, or of the ideas informing that system, is the increase of "undiagnosticated" cases submitted for the annual reports. This is shown by the following comparison:

UNDIAGNOSTICATED COMMITMENTS.

	In Massachusetts Hospitals.	In Danvers Hospital.	
1904	91	26	(29%)
1905	93	34	(37%)
1906	58	28	(48%)
1907	81	18	(22%)
1908	92	39	(42%)
	415	145	(35%)

For general reasons, therefore, the whole question of accuracy in the diagnoses of mental disease seemed to deserve opening up. I naturally resorted to the autopsied cases of the Danvers series, selecting those which had been passed upon by several diagnosticians at the daily clinics during life. During the years 1904–8, 247 cases had passed through the clinics and the laboratory and, for convenience in determining percentages, I added 3 cases also from the clinics of 1908, but autopsied early in 1909, making a series of 250 cases subject to anatomical review.

GENERAL PARESIS.

The task which lay nearest to hand was to determine our percentage of accuracy and the reasons for our errors in the group of *general paresis*. These data were presented before the American Neurological Association at its thirty-fifth annual meeting held in New York, May 27, 1909, and were later published in the *Journal of Nervous and Mental Disease*, January, 1910.

The conclusions of the work on general paresis were as follows:

1. An effort has been made to establish the accuracy of diagnosis in general paresis. The method has been to analyze clinically the data of cases in which several experienced workers had agreed upon the diagnosis, and to compare their findings with the anatomical and histological data of the autopsies.

2. Thirty-five out of 41 cases unanimously diagnosed general paresis *ante mortem* proved to be cases of general paresis (85% accuracy).

3. Six cases of erroneous diagnosis have been especially studied. None of these showed plasma cells in the nerve tissues (Nissl's methylene blue and L. Ehrlich's pyronin methods), but all showed a variety of lesions which warrant placing them in an "organic" group.

4. The lesions probably responsible for the errors in diagnosis were: (*a*) Meningomyelitis and subcortical encephalitis (luetic?) (Case V); (*b*) tabes dorsalis and non-paretic cerebral disease (Cases I, IV); (*c*) arteriosclerotic brain disease with severe cerebellar involvement (dentate nuclei) (Cases II, VI); (*d*) cerebral sclerosis (type, perivascular gliosis) (Case III).

5. Although at first sight a probable error of 15% in the diagnosis of general paresis might suggest difficulties in possible medico-legal cases, it is obvious that, were the diagnosis confined to "incurable insanity," or even to "organic brain disease," the error would disappear. However, 2 cases proved to be general paresis (on the plasma cell criterion) in a series of 186 cases similarly examined in which the diagnosis of general paresis was not considered.

6. Improvements in our diagnostic ability could perhaps be introduced by lumbar puncture and cytological examination in a greater proportion of cases. But it is doubtful whether three of the six errors here studied would have been resolved by cytodiagnosis (meningomyelitis, tabes dorsalis). One other case (VI, arteriosclerotic brain disease) actually did show plasma cells in the lumbar puncture fluid, the source of which was not made out at autopsy.

SENILE DEMENTIA.

At about the same time, I presented the results of a study of the *senile dements* of the same series (at the sixty-fifth annual meeting of the American Medico-Psychological Association, held in At-

lantic City, June 3, 1909). The conclusions of the paper, published in the *American Journal of Insanity*, April, 1910, were as follows:

1. Forty-two cases unanimously diagnosed "senile dementia" at the Danvers Hospital clinics have been reviewed clinically and anatomically, with a surprisingly low general percentage of accuracy (66%) where *either* cerebral atrophy *or* cortical arteriosclerosis or both were regarded as confirmatory, and with still lower percentages: 48% where cortical arteriosclerosis was considered essential and 38% where cerebral atrophy was considered essential for a correct diagnosis.

2. The 14 cases which showed neither cerebral atrophy nor cortical arteriosclerosis (with obvious damage to the cortical tissues) are cases which probably should not have been termed senile dementia and perhaps more properly belong in a group of acute psychoses or other mental diseases occurring in old age, but not dependent on recognizable senile changes.

3. Of the residuum, it is clear that cases in which cerebral atrophy and cortical arteriosclerosis are combined are not suitable for exact study, and attention has been concentrated upon 8 cases of relatively pure brain atrophy, regarded as representing more nearly genuine senile dementia than the arteriosclerotic cases, which should be classed under the head of organic dementia.

4. True senile or senile atrophic dementia includes (1) cases in which the loss in brain weight proceeds *pari passu* with a general loss of weight in the other viscera, and (2) cases in which the loss in weight of the nerve tissues is differential.

5. The mental diseases of old age, therefore, include (*a*) Mental diseases occurring in, but not characteristic of old age.

(*b*) Organic dementias due to cortical arteriosclerosis.

(*c*) Senile atrophic dementias, attended with (1) general visceral atrophy; (2) differential atrophy of the nerve tissues.

6. Obvious suggestions for research in the two groups of senile atrophic dementias, as above stated, are that the phenomena of general visceral atrophy may depend upon general decadent agencies (dehydration?) and that the more differential atrophy indicates special metabolic flaws or toxic agencies.

7. Since such a grouping has not been hitherto rigorously borne in mind, it is not possible to state the clinical features of these cases in detail.

8. Taking the group senile atrophic dementia as a whole, we find all the 8 cases female, without special indications of arteriosclerosis (in some instances not clinically made out), all showing the characteristic external signs of senility and all showing either chronic diffuse nephritis (interstitial type predominant) or renal arteriosclerosis.

9. Neurologically, the 8 cases showed characteristically *tremors*, absence of certain *superficial reflexes*, variations in some *deep reflexes* (tendency to loss of leg reflexes), *defective organic reflexes*, alterations of *gait* and occasional slight *speech* disorder.

10. Psychiatrically, communication with the patients is difficult and impressibility or general perceptual capacity was deficient. The amnesia for recent events is characteristic and constant. The patients are perhaps *unoriented* rather than disoriented. Amnesia for remote events is also frequently present. Delusions are not prominent. Visual or auditory hallucinations (or illusions) characterized some cases. Motor excitement and nightly restlessness and noise are characteristic, though not quite constant, and are not in all cases certainly due to hallucinations. Garrulity was surprisingly uncommon in this group.

11. Anatomically, the pia mater was in general remarkably free from chronic changes, and, as the condition of the vessels was the basis of selection of the cases, the vessels naturally showed nothing grossly beyond involvement of the larger or pipe arteries (basal cerebral arteriosclerosis). The cerebral wasting was not in all cases quite uniform. One case even showed a slight granular ependymitis. The consistence of the brain tissue was in general increased.

12. A high percentage of obsolete tuberculosis characterized the autopsies.

13. Aortic sclerosis is probably constant in these cases. Sclerosis of other vessels is frequent but variable. The constancy of renal changes is interesting.

14. The cause of death is pulmonary in many cases, and is perhaps in some way bacterial in all.

15. No intensive microscopic examination has been undertaken as the object has been rather to define the group of senile atrophic dementias. The satellite cell findings are consistent with Metchnikoff's hypothesis concerning phagocytic processes in old age. It is believed, however, that cell and fiber changes are very probably primary and "neuronophagia" secondary, or at any rate that these processes run *pari passu*.

16. A few cases showed satellite cells preferring the apical cell processes rather than the basal regions of the pyramidal cells.

17. It is alleged that no convincing evidence has been brought of a causal relation between *local* vascular changes and senile nerve cell atrophy.

It became obvious from these two pieces of work that psychiatry has been very unevenly developed. Already at a time when general paresis begins to present highly specialized problems, — perhaps the most interesting of which is the possibility of confusing cerebellar disease therewith, — senile dementia, on the contrary, suffers from a lack of clearness in its very definition.

My observations on the degree of accuracy which we *have* obtained — an accuracy surprisingly large if we consider the slender requirements of medicolegal practice at the present day — seemed to meet with a certain disapproval in the minds of those who do not favor hospital observation for medicolegal purposes. I, therefore, decided to study intensively the whole series of 250 non-selected cases from the daily conference records of 1904–8 and the subsequent autopsy and microscopic records of the Danvers laboratory. In the pursuit of this work I have enjoyed the facilities courteously afforded by the superintendent, Dr. C. W. Page, and the present laboratory staff, Dr. H. M. Adler, assistant physician and pathologist; Dr. Anna H. Peabody, assistant physician, and Dr. Myrtelle M. Canavan, assistant bacteriologist to the Danvers State Hospital.

The general statistics are as follows.

TABLE I.

	Cases.
Cases at daily clinics, 1904–8, later autopsied,	250
Clinical diagnoses unanimous,	184
Revised on autopsy data,	21
Opinions divided or doubtful,	66
Every opinion incorrect as shown by autopsy,	7
Remain as yet obscure,	10

Diagnostic Accuracy.

	Cases.
89% with all agreed,	184
74% some one correct,	66
85% some or all correct,	250

Of course I will not for a moment conceal that the above percentages of accuracy cover a multitude of minor sins of diagnosis.

These sins of diagnosis are not prominent in the paresis group and will be washed away effectively by the Wassermann method, which was not in use at the period of these diagnoses. (The cases of tabes without cortical exudate, but with mental symptoms, due to arteriosclerosis or to something else, will remain difficult to diagnose.)

But the troubles of the senile and organic dementia groups are not readily resolved. If I had counted as an error of diagnosis (1) each case in which the clinical diagnosis was senile, but the autopsy indicated organic dementia, and (2) each case in which the clinical diagnosis favored focal brain lesions, but the autopsy showed only diffuse brain atrophy, then our percentage of accuracy would be considerably lowered. As it stands, I have contented myself with counting as errors only those diagnoses which pointed to senile atrophy or arteriosclerosis, separately or combined, as the adequate cause of the mental disease in question, but in my opinion erroneously so pointed. I take it that medicolegal demands at the present day would insist on little more than this. On the other hand, I am of opinion that to ascribe mental symptoms to senile brain wasting or to cortical arteriosclerosis, when neither exists, is to make an error which might conceivably damage the patient's chance of recovery. *Conceivably*, I say, for it is probable that the aged can sustain just as irrecoverable mental disease in the absence of these coarse changes as can adults that are not senile. These considerations bring to the foreground the neglected field of senile acute (or functional?) psychoses.

If some one reviews in a similar fashion the diagnostic results of 1909–1913, he will doubtless find the conception of senile dementia somewhat clarified, and the standard both of clinical and of anatomical diagnosis raised.

The statistics concerning the separate forms of disease in the unanimous group are as follows:

TABLE II.

	Cases
Unanimous diagnoses,	184
General paresis, clinically,	42
" " anatomically,	36
" " errors,	6
Organic and senile dementia clinically,	80
Brain atrophy or cortical arteriosclerosis,	62
Tumor, lues, porencephaly, *general paresis*,	4
Total organic anatomically,	66
Errors — senile acute psychoses,	14
Total errors, general paresis,	6+1 = 7
" " senile psychoses,	14
	21

In the group of 184 unanimous diagnoses, there were, in addition to 42 general pareses and 80 senile or organic dementias, 62 other cases, including acute psychoses, certain functional conditions, alcoholic cases and the like. I have gone over these cases with considerable care, since a number of them have fallen in groups which have been especially studied for other purposes (terminal infections, dysentery and the like), and have so far found nothing inconsistent anatomically with the clinical diagnoses assigned. Particular attention has been given to the manic-depressive cases (a part of the series described summarily at the Rutland meeting of the New England Society of Psychiatry, Sept. 28, 1909, not yet published) and to the dementia precox group (some of the cases to be reported for the American Medico-Psychological Association, at its Washington meeting, 1910). The requirement for inclusion in the dementia precox group, anatomically, has been some degree of satellitosis of the deeper cortex-layers and either generalized induration or certain focal indurations of the central nervous system anatomically. Meantime I would not wish to say that future study might not considerably readjust the correlations in the group. In particular I have been struck with the small degree of anatomical disturbance which alcoholic insanity may be consistent with. For the present purpose, it is more pertinent to consider the group of cases in which opinions were divided or doubtful, the statistics of which are presented in

TABLE III.

Doubtful or obscure cases,		66
One or more diagnosticians right,		49
Organic and senile dementia,	19	
Acute psychoses,	14	
General paresis,	9	
Brain tumor,	4	
Miscellaneous,	3	
No diagnostician right,		7
(One case each of general paresis, cortical arteriosclerosis, organic dementia, streptococcus septicemia, epilepsy, streptococcus meningitis, cerebellar abscess.)		
Obscure both clinically and anatomically,		10
Acute psychoses (?),	6	
Alcoholic insanities (?),	2	
Deliria (?),	2	

The margin of cases that remain obscure is, therefore, 4%. In this connection it will be remembered that Abbot,[1] in his analysis of 14,770 admissions and discharges in Massachusetts hospitals for the insane, 1904–8, found 512 undiagnosticated, or 3.4%. Abbot observes, "The difficulties of diagnosis lie, chiefly between dementia precox and manic-depressive insanity, or between these and involution psychoses." This is well borne out in the "obscure" group of the present analysis, all of which probably belonged somewhere in the dementia precox group, the manic-depressive group or the toxic group, as adopted by Abbot. This obscure group will be worth more extended analysis at a future opportunity.[2]

Suffice it to say, for the present, that both the cases that remain obscure and those that became clear at autopsy give very definite warning in what field to work for the improvement of diag-

[1] Abbot: Forms of Insanity in Five Years' Admissions to, and Discharges from, the Hospitals for the Insane in Massachusetts. Am. Jour. Insan., lxvi, 1, July, 1909.

nosis. For, omitting the case of epilepsy (whose diagnosis became clear *intra-vitam* long prior to death), and 3 organic cases (all in some respects atypical, especially the one I have termed "organic dementia," a patient with Graves' disease and cerebral sclerosis), we remain with 13 cases, in many of which, if I am not mistaken, the methods of internal medicine might have arrived at a nearer guess.

I think it, therefore, not out of place to maintain that the duty which lies nearest the modern psychiatric clinic is to adopt and develop, so far as possible, the methods which prevail in the best general hospitals, and employ them alongside the special neurological and psychological methods which more obviously, but not more indispensably, belong to psychiatry. That is to say, the modern psychopathic hospital must resolutely face the problems of what has come to be termed *clinical pathology*, a kind of pathology in which the autopsy is sometimes the *end*, but assuredly not the *aim*, of work.

Clinico-pathological studies of acute mental cases, *particularly in their first attacks*, may well unearth facts of commanding importance in psychiatry.

SUMMARY.

1. A series of 250 cases of mental disease, with *intra-vitam* diagnoses by several physicians, recorded at the Danvers State Hospital daily clinics, 1904–8, has been subjected to anatomical review for the sake of learning where lie the greatest difficulties in diagnosis.

2. Ten cases (4%) remain both clinically and anatomically obscure.

3. Seven cases (2.8%) had diagnostic doubts settled after the clinic either *intra-vitam* or *post-mortem* (one case each of general paresis, cortical arteriosclerosis, cerebral sclerosis with Graves' disease, streptococcus septicemia, epilepsy, streptococcus meningitis, cerebellar abscess).

4. Sixty-six cases (26%) were doubtful clinically, but the correct diagnosis was obtained by one or more diagnosticians in 49 of the 66 (74% of the doubtful group).

5. One hundred and eighty-four cases (74%) were clinically certain, and the clinical diagnoses were confirmed (or not altered) by autopsy in 163 of the 184 (89% of the unanimous group).

6. The correct diagnosis was obtained by one or more diagnosticians in 49 + 163 = 212 cases in 250 (85%).

7. The "correctness" of these diagnoses is subject to some reservation, (1) since within the "organic and senile dementia group" differentiation proved difficult, and (2) since anatomical "consistency" often signifies absence of characteristic lesions. The acute psychoses have been reviewed, however, bearing in mind modern views. Several alcoholic cases failed to exhibit striking brain lesions.

8. The majority of the real diagnostic difficulties uncovered by this analysis would appear to require more intensive work in the field of clinical pathology. For such work in psychopathic hospitals, this paper is an appeal.

III.

A Study of the Dementia Precox Group in the Light of Certain Cases Showing Anomalies or Scleroses in Particular Brain Regions.*

BY E. E. SOUTHARD, M.D.

Contents.

I.

THE SCHISM OVER DEMENTIA PRECOX.

Intoxication or dissociation.
Apparent hopelessness of cortical cytopathology.
Satellitosis of the deeper cortex layers (Alzheimer).
French confirmation.
Sioli's findings.
Alzheimer's proof that dementia precox is an organic psychosis.
Differentiation possible between katatonic and maniacal excitement.
Similar disintegration products in the brains of katatonia and of toxic delirium or severe visceral disease.
Hirntod.
Terminal infections in the insane remarkably common (Danvers data).
Acute cytopathological changes must remain hard to interpret.
Stratigraphic alterations (deep-layer satellitosis) important, but also not differential.
The topographic idea in the anatomical investigation of dementia precox.

II.

MATERIAL, WITH STATISTICAL ANALYSIS.

Sixty-three cases of probable or possible dementia precox.
Classified by age at death.
By age at onset.
By duration of symptoms,
Superficial analysis into forms.
Brain weights by sex.
By age at death.
By clinical forms.
By duration of disease.
Heart, liver, spleen and kidney weights.
Summary.

III.

GROSS ANATOMICAL ANALYSIS OF THE BRAIN FINDINGS.

Object of the analysis.
Exclusion of cases of coarse cerebral atrophy from prior consideration.
Exclusion of cases showing focal destructive arteriosclerotic lesions.
Exclusion of cases of chronic diffuse leptomeningitis.
Dural and calvarial conditions.
Nineteen out of thirty-seven cases show macroscopic lesions.
Pre-Rolandic group.
Post-Rolandic group.
Infrasylvian group.
Cerebellar group.
Other macroscopic cases.
General grouping: (1) complicated cases (excluded from prior consideration) (40%), (2) cases with minor macroscopic lesions (31%), (3) cases without observed macroscopic lesions (29%).
Clinical analysis of 37 chosen cases, with elimination of 8.
Fifty-two per cent of non-complicated chosen series show macroscopic lesions.
Incidence of tuberculosis in this series.
Incidence of other somatic complications.
Summary.

* Read in part at the Washington meeting of the American Medico-Psychological Association, May, 1910.

IV.

CLINICAL AND ANATOMICAL ANALYSIS OF FIFTEEN CASES OF DEMENTIA PRECOX SELECTED AS SHOWING CERTAIN MINOR GROSS LESIONS OF THE NERVOUS SYSTEM.

Correlations.
Condensed histories and autopsy protocols in 15 cases.
The question of congenital anomalies *vs.* acquired lesions.
Summarized impressions of each case.
Acquired lesions probable in 14, congenital in 8, of 15 cases.
Anatomo-clinical correlations.
Pre-Rolandic group, with frontal-paranoid correlation.
Post-Rolandic group.
(*a*) Postcentral, superior parietal, katatonic correlation.
(*b*) Occipital subgroup.
Infrasylvian group.
Cerebellar group, katatonic.
Provisional grouping of 14 cases without recorded gross lesions.
Four cases in which gross lesions *should* probably have been recorded.
Probable actual proportion of gross lesions in our series, 68%.
Necessity of intensive inspection *and palpation* of brains at autopsy.
Probable actual proportion of gross and microscopic lesions in our series, 86%.

V.

THE TOPOGRAPHIC IDEA IN THE STUDY OF DEMENTIA PRECOX AND ALLIED CONDITIONS.

Brain "changes" in functional psychoses.
Is insanity brain-disease?
If insanities are brain-diseases, the brain-*parts* involved should be specified.
Wernicke's generalization.
The diabetes mellitus analogy — mental symptoms not necessarily cerebral, as glycosuria not renal in origin.
Universal cytopathological changes not likely in dementia precox.
Analogy of dementia precox and general paresis.
Random blocks of brain tissue, showing satellitosis, infrastellate gliosis or disintegration products, not likely to solve problems of pathogenesis of symptoms.

VI.

CONCLUSIONS.

I. THE SCHISM OVER DEMENTIA PRECOX.

When it became apparent that the psychiatric world must needs split over the genesis of dementia precox, one party describing it as a species of intoxication with brain damage and the other as a dissociative mental disease without structural damage to the brain, one found one's mind almost wholly open in the matter. Perhaps, at the outset, one was not quite ready to admit dementia precox (Kraepelin's disease) among such relatively immortal entities as general paresis and hysteria, for example. The dissociation hypothesis possibly seemed the wider of the two, permitting each case to be a law unto itself in such wise that a proper diagnosis really turned into a fairly full katamnesis.

In any event, it was gratuitious to hypothecate a toxin *toto coelo*, and much more innocent to assume dissociations, especially if one could give precise descriptions of these for a number of typical cases. To be sure, some workers asserted characteristic satellitoses and other evidence of neuronic disease in the lower cortex-layers of the cerebrum; but these findings were perhaps inconstant, probably shared by other types of disease, possibly secondary either to the disease or to something else and certainly incapable of affording any explanation of the mechanism of dementia precox.

If one scanned the situtation in neuropathology, the outlook was not bright. Restricting oneself to the cerebral cortex alone, cytopathology appeared to have fallen on evil days. Nissl had given up his specific nerve-cell intoxication pictures. Alzheimer's methods for split products of nerve-cell metabolism had not been developed or fully applied. And, in any case, the effects of terminal complicating disease (intestinal, pulmonary, bladder and the like) with a variety of intercurrent infections and intoxications seemed to render dubious the outcome of almost any strictly cytopathological study, at least such as would contemplate symptomatic correlations. To conceive a "katatonic storm" sweeping through the cortex and leaving behind it a characteristic trail was within reason, but surely difficult of proof in the midst of so many cortical "storms" about the point of death.

Stratigraphic considerations were more hopeful. In fact, ever since Alzheimer's brief paragraph in 1897, — *Ebenso findet sich ganz zweifellos bei der Katatonie eine pathologische Gliafaserbildung in der Rinde, anscheinend auf gewisse Rindenschichten (und die Markleiste) beschränkt*,[1] — there has been an ever-recurrent assertion that satellitosis and correspondent nerve-cell disorder of the inner cortex-layers are characteristic of dementia precox, or at least of its katatonic form. In fact, these findings were supposed to draw together the two diseases, dementia precox and general paresis, since both showed the same changes, complicated in the latter by a multitude of other stratigraphic changes as well as by exudation.

Such opinions are not confined to Germany. Thus, in France, Klippel and Lhermitte, 1908,[2] consider dementia precox to be due to a progressive atrophy of the association neurones. The lesions of dementia precox, they say, are all essentially neuro-epithelial, i. e., confined to nerve-cells and neuroglia, and never essentially vasculo-conjunctive; or, as we should express it, ectodermal, never mesodermal. The fundamental lesion is "a regressive atrophy of the nerve-cells of the deep cortical layers and disappearance of the interconnecting processes," with neuroglia proliferation running *pari passu* with atrophic process. Meningovascular lesions, miliary hemorrhages, congenital malformations, terminal lesions due to cachexia or infection, are frequent, but are not indispensably found. Even cerebellar atrophy, and various instances of visceral hypoplasia, are simply signs of frail organisms, which either precede without causing dementia precox or are purely incidental effects thereof. Klippel, in discussion, admitted that similar neuro-epithelial (ectodermal) lesions were found in other chronic mental diseases.

Perhaps no work has been more widely quoted in this direction than that of Sioli, done partly at Munich under Alzheimer and partly at Bonn, and summarily reported in 1909. Sioli's statements

refer, however, only in part to stratigraphic considerations.

Sioli, in his brief *Autoreferat*, 1909,[3] states that he found *in all parts examined* of 20 cases of dementia precox certain evidences of destruction of nerve tissue. A portion of Sioli's data is cytopathological (nerve-cell disease with increase of Scharlach-stainable lipoids), but he indicates that the process may lead to atrophy or disappearance of cells, amounting in places to distinct stratigraphic disorder. Degenerative products were found accumulated in clear non-cellular spaces about the vessels, and protagonoid and Scharlach-stainable substances were found in tissues and in adventitial cells *en route* to the vessels. Inflammatory exudation was quite lacking. Perivascular and periganglionic glia-cell proliferation, fibrillary gliosis in the subpial zone, in deep cortex-layers and in the white matter, alterations of glia cell cytoplasm, ameboid neuroglia in the white matter occurred. The severest cases, especially those with their perivascular spaces packed with degeneration products, are thought to correspond with acute katatonic exacerbations.

Alzheimer, in his masterly statement concerning split products of nerve-cell and fiber metabolism, 1910,[4] maintains that much new light has been thrown, by his new methods and adaptations of old ones, upon such conditions as status epilepticus, severe paralytic attacks, deliria and katatonic excitements, and he believes that any one using these methods will be convinced that dementia precox and epilepsy are severe organic diseases. Alzheimer would almost risk differentiating histologically between a katatonic excitement and a mania because the katatonic case will show characteristic ameboid glia cells whereas the mania will not. For the purposes of this differentiation, severe disease of the other viscera must not step in to complicate the picture, since such disease may bring out the ameboid glia cells in the nervous system. Again, a severe toxic delirium at its height and a severe katatonic excitement at its height will exhibit similar changes (just as the posterior columns of a tabes and of a spinal transsection might be confused under certain circumstances from the granule-cell content of both). The fact seems to be that "organic" changes can now be demonstrated in a number of conditions formerly termed "functional." The differentiation of katatonia remains difficult, however, on account of precisely the conditions mentioned by Alzheimer, — toxic delirium and severe bodily disease, — which may produce somewhat the same pictures.

One remarkable case of sudden death in a stuporous katatonic who had no demonstrable physical disease is mentioned by Alzheimer to show that, without loss of any nerve-cell or degeneration of a single axis-cylinder, a true *Hirntod* may occur due to changes demnostrable by methods for the split products.

Unfortunately for the neuropathologist, such cases of pure *Hirntod* are rare. In the Danvers State Hospital material, infection at the time of death is almost the rule. Exact experiences with the cultivation of the more easily growing organisms from the blood and cerebrospinal fluid in 150 unselected cases have been communicated by Gay, Canavan and myself.[5,6] Cerebrospinal fluids are particularly prone at death to show organisms. This experience, as well as an inspection of the great numbers of tuberculous and acute infections in our material, caused us to discount in advance the cytopathological change *per se* and to hold somewhat in doubt the acute or recent neuroglia change as indicating mental disease. The asserted stratigraphical changes (cell-atrophies and losses in lower cortex-layers and correspondent satellitosis) seemed more trustworthy, but obviously less differential (seen also in general paresis and in some senile cases).

The status of the dementia precox question may be summed up as follows:

One body of workers prefers to describe dementia precox in such terms as *dementia sejunctiva* (Gross [7]), *Misserhältniss zwischen Affekt und Vorstellung* (Kölpin [8]), *dysphrenia* (Wolff [9]), *dementia dissecans* (Zweig [10]), *schizophrenia* (*Zerreissung oder Spaltung der psychischen Funktionen*) (Bleuler [11]), *apraxia ideatrix* (Dromard [12]), emphasizing in general the dissociative factors which emerge upon psychological analysis of the more clearly cut cases. "Disruptions of judgment," "specific factors in individual cases," "unpsychological reactions," "intrapsychic ataxia" or, more specifically, "noothymopsychic ataxia," "intrapsychic inhibition," "psychogenic conflicts," "psychological dispositions," "psychic causes," "psychic trauma," are phrases picked almost at random from certain modern discussions.[13,14,15]

Other workers pin their faith to the supposed "organic" character of this disease. The ground of this belief is often scarcely more than that the disease is essentially deteriorative on the mental side and hence *must* be "organic" on the cerebral side. Others set much store by auto-intoxication and believe that the effects of auto-intoxication must be registered in the cerebral cortex, could we but read it aright. Proceeding from the dictum that insanity and, therefore, dementia precox are brain diseases, these workers argue that dementia precox is presumably a destructive disease of the cerebral cortex after the manner of general paresis.

A few workers accord significance to both the functional psychic features and the organic cortical features. There is, however, a general tendency to take sides, with the almost universal feeling that the histologists have not satisfactorily proved the "organic" nature of the disease.

I was instigated to the analysis of my own material by the conviction that, though the histopathologists had not proved their point beyond peradventure, the functionalists were in the same plight. I had been engaged upon an analysis of cases of mental disease with onset after the fifieth year,[16,17] and had there come upon so many instances of satellitosis in the deeper layers of the cortex without distinct katatonic features clinically that I had been disposed to discount

the differential character of deep-layer gliosis for any type of mental disease. This reaction, in brief, appeared to be a necessary and natural result of destructive processes involving these layers, and the deposition or increase of neuroglia cells in this locus did not assume to my mind the differential character of such findings, as, e. g., the plasma-cell exudate of general paresis. Even the plasma cell, as all will admit, is not, *sensu strictiori*, pathognomonic for general paresis (witness trypanosomiasis, not to mention tuberculous and frankly luetic processes). Gliosis of the deep layers of the cortex is obviously far less differential than plasma-cell exudation, if only because normally we find neuroglia and satellite cells in this region.

Feeling a deal of uncertainty about the differential value of stratigraphic alterations, and especially of satellitosis, I was also not disposed to believe that dementia precox would turn out to be a diffuse cell disease. All that Alzheimer maintains, if I understand him aright, is that any one who chooses to examine dementia precox material by certain methods can convince himself that it is invariably an "organic" disease.[18] It would be a much longer step to assert that the changes invariably found are differential changes. Indeed, deliria and severe physical disease are consistent with the same changes.

Neither stratigraphic changes nor cytopathological changes, taken as exhibited *throughout a brain*, appealed to me as likely to throw much light on the immediate mechanism of dementia precox. Indeed, these changes bring up more new problems than they solve old ones in the wide field of neurobiology.

The *topographic idea* then occurred to me. In making, some years ago, an analysis of the first 1,250 autopsies of the Danvers State Hospital, and collecting the lesions of different parts of the brain in card-catalogue form, I had been much struck with the preponderance of brain lesions in certain areas. The frontal incidence was particularly high, and this I took to be due to the greater lability of the frontal tissues (on the stock evolutionary grounds). Having no convenient opportunity to correlate these findings with clinical data (a want now happily supplied by the index of clinical symptoms which Dr. Page has had constructed), I did not further work up these relations.

In connection, however, with work on encephalitis,[19] on gliosis,[20,21] and especially on the "soft brain,"[22] I had begun to gather unusually careful data concerning focal and general variations in consistence of brains. I had, therefore, some hope that my series would prove unusually suitable for topographic study.

Upon analysis, as the sequel will prove, not merely focal scleroses, but also easily identifiable macroscopic atrophies (or aplasias) were found in a surprisingly large number of cases. My topographic data depend, therefore, only in part upon the palpable mild scleroses which I had been especially studying.

On the basis of the anatomical data, and without necessarily any reference to microscopic studies (which have been carried out more or less thoroughly in the series), I wish to commend the topographic idea concerning lesions in dementia precox to neuropathologists. Whether a superior frontal atrophy or a post-central aplasia is or is not superior to a psychic scar or ataxia, as really explanatory of the mechanism of dementia precox, I will not pretend to say. In any event, the brains of all dementia precox cases should be carefully examined.

II. MATERIAL WITH STATISTICAL ANALYSIS.

The autopsy material of the Danvers State Hospital Laboratory from May, 1902, to January, 1910 (including the services of Dr. A. M. Barrett, E. E. Southard, and a portion of Dr. H. M. Adler's), consists of 647 cases. Sixty-three of these have been chosen on clinical grounds as probable or possible examples of dementia precox. The 10% thus chosen constitute the maximum rather than the minimum number of possible cases, since it was thought best to include certain doubtful cases for purposes of comparison. As will presently appear, several of the cases are so clouded by other factors, such as certain congenital features, alcoholism or attacks suggestive of manic-depressive insanity, that the diagnosis of dementia precox may appear extremely doubtful. It was felt that histological features might serve to extract the true cases.

As it is extremely desirable not to confuse phenomena of a normally aging brain with possible findings based on mental disease, the age of the subjects at death is important. The series is quite representative.

TABLE I.

Classified by decades according to age at death, the material shows:

Cases Dying.	Decade.	Ages.	Male.	Female.
11	3	21–30	8	3
19	4	31–40	7	12
12	5	41–50	3	9
11	6	51–60	6	5
8	7	61–70	7	1
2	8	71–80	2	0
63		21–80	33	30

It is also necessary to secure a representative series from the standpoint of age at onset. The series even includes two cases with strongly congenital coloring.

TABLE II.

Classified by decades according to age at onset, the material shows

Cases.	Decade.	Ages.	Male.	Female.
6	2	11–20	6	0
28	3	21–30	13	15
20	4	31–40	9	11
7	5	41–50	3	4
2	congenital features (possible imbecile),		2	0
63			33	30

It is essential to know how long the morbid process may be supposed to have lasted. Although many of these cases are not at all progressive, yet in many others slow transitions in clinical disease-type are exhibited. The total durations are given in

TABLE III.

Classified by duration of symptoms in hemidecade periods, the material shows

Cases.	Ages.	Male.	Female.
18	under 5	8	10
11	6–10	5	6
10	11–15	3	7
3	16–20	2	1
7	21–25	4	3
4	26–30	2	2
3	31–35	3	0
3	36–40	2	1
1	41–45	1	0
2	46–50	2	0
1	61–65	1	0
63		33	30

Although it is well known that various clinical phenomena are rather thoroughly commingled in this disease, making the older distinctions hard to maintain and more or less justifying Kraepelin in his union of types under a single caption, yet certain features do particularly characterize some cases, and the following table presents the impressions which these cases made, so to say, in the rough, before intensive analysis.

TABLE IV.

SUPERFICIAL ANALYSIS OF CASES.

	Cases.	Male.	Female.
Hebephrenic,	5	2	3
Katatonic,	17	9	8
Paranoid,	30	18	12
Dementia-precox-like:			
Imbecile,	1	1	0
Alcoholic,	1	1	0
Manic-depressive, involutional and unclassified,	9	3	6
	63	34	29

There was such an admixture of symptoms in several of the cases, or symptoms of doubtful import, that possibly the katatonic cases should number 20, and the paranoid cases 32. Imbecile traits came in question in 7 cases in all, though possibly not to obscure the eventual diagnosis in more than 3. Alcoholism can with difficulty be disengaged from the clinical picture of 5 cases. The at times doubtful or eventually unclassified cases which have been chosen to study with this group number 15, but of these perhaps 8 only can be fairly claimed as not instances of dementia precox; and, if a somewhat liberal definition be admitted, all these cases will warrant consideration. As Table IV indicates, 52 cases (29 male, 23 female) probably belong in the group with some certainty on clinical grounds.

In the process of anatomical analysis, much may be gained from the weight-correlations of certain organs. If the brain-weights stand up well, we at least have indication that no such conditions as those underlying general paresis or cerebral atrophy are present. The brain-weights in this series correspond well with the normal, though they show a slight tendency to reduction (2%).

TABLE V.

BRAIN WEIGHTS BY SEX.

	Dementia Precox. Gm.	Normal (Viercordt). Gm.
Male (26 cases),	1,336	1,357
Female (29 cases),	1,218	1,235
Differences,	118	122
Percentages:		
Male,	98%	100%
Female,	98%	100%

An analysis of the brain-weights according to age at death yields by no means so even a curve, doubtless because the numbers are too small for this particular purpose. The results are as follows:

TABLE VI.

BRAIN WEIGHTS BY DECADES IN WHICH DEATH OCCURRED.

	Cases.	Dementia Precox. Gm.	Normal (Boyd). Gm.
Male, 21–30,	6	1,333	1,358
Female, 21–30,	3	1,278	1,239
Male, 31–40,	5	1,476	1,366
Female, 31–40,	11	1,194	1,222
Male, 41–50,	3	1,350	1,348
Female, 41–50,	9	1,237	1,244
Male, 51–60,	6	1,353	1,345
Female, 51–60,	5	1,222	1,225
Male, 61–70,	5	1,364	1,315
Female, 61–70,	1	1,100	1,210
Male, 71–80,	1	1,390	1,290

It might be suspected that the different forms of dementia precox would lead to different degrees of brain-weight reduction. The weights in the hebephrenic, katatonic and paranoid cases, in accordance with the clinical analysis of Table IV, have been arranged.

TABLE VII.

	Cases.	Dementia Precox. Gm.	Normal (Viercordt). Gm.
Hebephrenic:			
Male,	2	1,338	1,357
Female,	3	1,168	1,235
Katatonic:			
Male,	9	1,329	1,357
Female,	8	1,193	1,235
Paranoid:			
Male,	12	1,309	1,357
Female,	11	1,240	1,235

The differences are all less than 70 gm. and the weights are consequently within 5% of the assigned normals.

Since the duration of the disease, though it certainly does not vary with the duration of any active process in all cases, might be supposed to bear some relation with the extent of any destructive process, the weights have been arranged according to duration:

TABLE VIII.

	Dementia Precox.	Normal (Vierordt).
Cases with duration under 10 years:		
Male,	1,331	1,357
Female (16 cases),	1,223	1,235
Cases with duration 11–20 years:		
Male (5 cases),	1,261	1,357
Female (7 cases),	1,243	1,235
Cases with duration over 20 years:		
Male (10 cases),	1,375	1,357
Female (6 cases),	1,173	1,235

Obviously these figures produce no even curve, but, should they be confirmed by other material, the inference could certainly be drawn that these brains stand wear and tear particularly well.

If such figures tend to show that no coarse katabolic effects evince themselves in the brains of this group, it is interesting to inquire whether any evidence of such disorder can be traced in other organs by this method.

TABLE IX.

HEART WEIGHTS.

	Dementia Precox.	Normal (Vierordt).
Male, (31 cases)	281	
Minus 3 hypertrophies (500+ g.),	244	313
Female (27 cases),	264	
Minus 1 hypertrophy,	253	310

TABLE X.

LIVER WEIGHTS.

		Normal (Vierordt).
Male (30 cases),	1,369	1,579
Female (28 cases),	1,257	1,526

TABLE XI.

SPLEEN WEIGHTS.

		Normal (Vierordt).
Male (30 cases),	160	
Minus 1 case wt. 870,	132	149
Female (27 cases),	106	180

TABLE XII.

COMBINED KIDNEY WEIGHTS.

		Normal (Vierordt).
Male (31 cases),	280	277
Female (29 cases),	255	264

Tables IX to XII appear to show that certain organs of the trunk are more disposed to evince losses in weight than is the brain. The kidney weights, however, stand up well. The weight of the spleen, as always, showed marked variations, and these variations largely depend probably on certain terminal conditions independent of mental disease.

Reductions in average weights of heart and liver reach a little over 8% for both males and females in both series. It is hard to draw a significant conclusion therefrom.

To sum up the data of this section, we learn from a fairly representative series of cases of dementia precox and similar disease that a reduction in brain weight of 2% is perhaps to be expected in the total group, that the reductions in brain weight of 5% occur in certain forms (here a larger number of cases is required for deductions), that the brain weights do not undergo progressive reduction with the duration of the disease, and that the hearts and livers of the series show in general a reduction of 8% in weight. Since the weights of the trunk viscera probably vary rather uncontrollably in the present state of knowledge (the factors of muscular activity and of nutrition in these patients come particularly in question), it is plain that more stress must be laid on brain conditions. The brains must be approached, therefore, with the premonition that changes, if any, will be fine changes, and possibly qualitative and transformatory rather than destructive.

III. GROSS ANATOMICAL ANALYSIS OF THE BRAIN FINDINGS.

As it is our object to show *either* first that there are no characteristic brain findings in this series of cases, *or*, secondly, that there are characteristic findings common to the series, it is obviously necessary to exclude cases with certain features which we are sure are not characteristically allied with dementia precox. Such complicating features are *coarse cerebral atrophy* and *regionary arteriosclerosis*. These features complicate and sometimes influence the course of dementia precox, but it is certain that arteriosclerosis, and highly probable that coarse cerebral atrophy are not characteristically associated with the disease.

As is well known, the question whether brain atrophy exists cannot be safely answered from the brain weight alone, since apparently high weights are consistent with atrophy of originally large brains, and apparently low weights may mean simply that the original weights were low. Qualitative data are safer guides here.

Five brains gave the qualitative impression of *generalized atrophy*. All these cases were of long total duration (eleven years or more).

It seems safe to eliminate this group from prior consideration, despite the fact that the gliosis shown may be more or less closely related with dementia precox.

One of the best indices of damaging local arteriosclerosis is afforded by *cysts of softening*, which were found in three cases, 1274 and 1297 of Table XIII, and 1171 (5986, female, forty-three, paranoid, duration seventeen plus [thirty?] years, brain weight, 1115 gm.), also excluded from prior consideration.

TABLE XIII.

Autopsy Number.	Clinical Number.	Sex.	Age.	Disease-Type.	Duration.	Terminal Disease.	Brain Weight. Gm.
752	9888	F.	64	Hebephrenic	39 years	Pneumonia, 7 days	1,100
958	10738	F.	37	Paranoid	11 years	Exhaustion, 1 month	1,210
1266	7559	F.	58	Paranoid	13++ years	Dysentery, some weeks	1,250
1274	11027	M.	56	Katatonic	31 ± years	Hemiplegia, 1 month	1,365
1297	7511	F.	47	Paranoid	19 years	Cancer of uterus, 2+ months	1,390

Also it may be safer at first to exclude seven cases (1099, 13180, male, sixty-seven; 1121, 13398, female, fifty-six; 1174, 9769, female, forty-eight; 1258, 2, male, sixty-four; 1270, 617, male, sixty-eight; 1337, 15017, female, forty-five; and 1368, 121120, male, fifty-six) on the score of *marked sclerosis of vessels of the circle of Willis*. It is certain that this sclerosis has no direct effect upon the mental life; but there is at least a suspicion of vascular disease in the finer branches in such cases (only two of which in this series, viz., 1337 and 1174, are under fifty-six years of age).

It is noteworthy that we are required to exclude on these grounds (grounds, namely, of complicating "organic" brain-disease) only about 20% of our series. This confirms the impression gained from our statistical analysis of the brain weights. There is another general condition frequently found in cases of all descriptions (both sane and insane), which might be considered to have some bearing especially upon the histology of the superficial layers, *chronic leptomeningitis of diffuse distribution* (to the focal distributions we shall return in a moment). Eleven cases (842, 904, 913, 943, 958, 1014, 1025, 1027, 1093, 1234, 1338) may be excluded on this ground. These eleven and four others (already excluded) yield another perhaps surprisingly small percentage (about 22%) of cases showing diffuse chronic leptomeningitis.

For completeness are also presented the data concerning

TABLE XIV.

DURAL AND CALVARIAL CONDITIONS.	Cases.
Arachnoidal villi unusually developed,	3
Thickening of dura mater (not included under adhesions),	4
Chronic internal hemorrhagic pachymeningitis,	3
Dense calvarium,	9
Thick calvarium,	6
Thick and dense calvarium,	2
Thin calvarium,	3
Calvarial adhesions of the dura mater,	25

If we rely upon the statistical analysis of Section II, we cannot be so sure that *mild focal lesions of an atrophic or sclerotic nature* have nothing to do with processes in dementia precox, since these lesions will not appreciably influence brain weights. It is, of course, *a priori*, unlikely that such circumscribed foci, which are doubtless in the vast majority of instances due to some degree of local tissue destruction, can correspond with the extended series of vital reactions which we term dementia precox. Nevertheless, it is wise to examine our series carefully for foci of a slightly destructive or perhaps purely irritative character which might bear on the course of certain cases.

Consequently, excluding as diffusely atrophic 5 cases, as markedly arteriosclerotic (cysts of softening or basal cerebral arteriosclerosis) 8 cases, as showing diffuse chronic pial changes 11 cases, we remain with a material of 39 cases which deserve primary consideration from the standpoint of *possibly significant focal brain lesions*. Obviously the results of the search in these 39 cases (2 of which must be excluded through inadequate protocols) may be applied with due caution to the remainder.

A group of 12 cases amongst these 37 "non-organic" cases showed certain *minor lesions* made out in the gross, but *not frankly destructive, some possibly congenital in origin*. A summary view of these cases is presented in

TABLE XV.

MINOR MACROSCOPIC BRAIN LESIONS IN DEMENTIA PRECOX.

Autopsy Number.	Clinical Number.	Sex.	Age.	Disease-Type.	Duration.	Frontal Lobe Lesions.
I. *Pre-Rolandic Lesions.*						
840	11211	F.	38	Katatonic	3 years	Atrophy and gliosis of frontal lobes
1062	7987	F.	38	Paranoid (alcoholic)	11 + years	Gliosis of superior frontal, prefrontal and orbital gyri
1143	8823	F.	47	Paranoid or katatonic	10 years	Gliosis of frontal, including orbital, gyri (see also cerebellum)
1294	10862	F.	37	Paranoid	6 years	Frontal lobe gliosis (see also post-Rolandic and cerebellar groups)
1310	13582	F.	28	Hebephrenic mannerisms	4 years	Frontal lobe gliosis (see also post-central group)
1358	10580	M.	24	Katatonic	10 years	Gliosis of left inferior frontal lobe
1360	10168	M.	51	Suicidal	10 years	Atrophy of prefrontal gyri
II. *Post-Rolandic Lesions.*						
1137	6531	M.	35	Paranoid, later katatonic	15 years	Right superior parietal microgyria (atrophy?)
1168	11863	F.	24	Hebephrenic, paranoid?	3½ years	Bilateral aplasia of post-central gyri
1298	14591	F.	36	Katatonic	10 months	Right post-central atrophy (see discussion)
1310	(See Frontal Group)					Left post-central aplasia or atrophy
1294	(See Frontal Group)					Occipital region gliosis
1149	11641	M.	57	Paranoid	32 years	Occipital region gliosis
1317	12143	F.	44	Paranoid	21 years	Occipital microgyria
III. *Infra-Sylvian Group.*						
1319	14597	F.	31	Paranoid (imbecile?)	8 years	Superior temporal anomaly

IV. *Cerebellar Lesions.*

Autopsy Number.	Clinical Number.	Sex.	Age.	Disease-Type.	Duration.	Frontal Lobe Lesions.
1034	12756	M.	35	First paranoid, later katatonic	2 years	Sclerosis of dentate nuclei of cerebellum
1143	(See Frontal Group)					Sclerosis of right dentate nucleus, culmina, and clivi of cerebellum. Pons and olives firm
1168	(See Post-Rolandic Group)					Sclerosis of right dentate nucleus, cacumina, and clivi of cerebellum. Sclerosis of olives

A somewhat similar small group of four cases has shown certain appearances in the spinal cord indicating abnormality of quite doubtful interpretation.

If we eliminate the alcoholic (1240, no gross lesions) and doubtful cases (819, 939, 1151, no gross lesions; 1143, 1360, frontal lobe lesions; 1350, spinal cord lesion; 1135, generalized gliosis

TABLE XVI.

GROSS LESIONS OF THE SPINAL CORD.

Autopsy Number.	Clinical Number.	Sex.	Age.	Disease-Type.	Duration.	Gross Lesions of the Spinal Cord.
1317	(See Post-Rolandic Group)					Cervical portion abnormally firm
1319	(See Infra-Sylvian Group)					Cervical cord abnormally large
1335	(See Table XVII)					Cord abnormally small
1350	4820	M.	62	Katatonic	35 + years	Gliosis of lumbar spinal cord

Here, then, as indicated in Tables XV and XVI, is a group of fifteen cases showing certain minor chronic lesions (or evidences of aplasia) in the central nervous system of quite doubtful, though certainly very varied, origin. Adding four more cases of *generalized cerebral sclerosis* of a mild form, not associated with gross atrophy, viz.

[compare Tables XV and XVI]) for the time being, we obtain 52% of our group (now reduced to 29 cases) showing minor lesions.

A microscopic analysis of the 15 cases showing minor lesions may indicate what type of lesion to look for in those cases which failed to show gross lesions. Lesions of this sort should be demonstra-

TABLE XVII.

Autopsy Number.	Clinical Number.	Sex.	Age.	Disease-Type.	Duration.	Brain Weight. Gm.
991	11047	M.	35	Paranoid	11 years	1,170
1135	11296	F.	28	Katatonic	6 years	1,430
1303	11624	F.	55	Hebephrenic	25 years	1,220
1335	13648	M.	32	Katatonic (alcoholic)	20 years	985

we obtain a total of *nineteen cases of slightly, though macroscopically, abnormal central nervous system in a series of thirty-seven cases, selected as not showing coarse complicating features like brain atrophy, intracranial arteriosclerosis, cysts of softening and the like.*

These nineteen cases, or at all events a certain number of them, demand attention as a group of dementia precox cases with lesions of doubtful interpretation, but not readily set aside as non-significant.

If we should group our cases up to this point we should obtain (1) *complicated cases* showing gross lesions certainly not related with dementia precox, 40%; (2) *cases with minor lesions* having a doubtful relation to dementia precox, 31%; and (3) a residuum of *cases without observed gross lesions*, 29%.

It will be wise at this point to analyze the cases of groups (2) and (3), i. e., the non-complicated cases, from a clinical point of view. The 37 cases are distributed as follows:

TABLE XVIII.

	Cases.	Male.	Female.
Hebephrenic,	4	2	2
Katatonic,	12	5	7
Paranoid,	13	7	6
Alcoholic,	1	1	0
Doubtful,	7	3	4

ble by any method which displays cells and nuclei well.

In case the lesions should prove non-stratigraphical, i. e., not ideally demonstrable by complete cell counting, the task will be more difficult. The qualitative intracellular or special extracellular properties which this latter search would entail will require material very seldom obtained, material free from terminal complications. Cases hitherto reported have suffered perhaps from such terminal disease. Tuberculosis is a special offender in this direction. Tuberculosis occurred in our series as follows:

TABLE XIX.

TUBERCULOSIS IN 63 CASES OF DEMENTIA PRECOX.

	Cases.
Active forms,	21
Healed and chronic forms,	16
All forms,	37

TUBERCULOSIS IN 39 CHOSEN CASES.

	Cases.
Active forms,	16
Healed and chronic forms,	7
All forms,	23

In both series there is 58% of tuberculosis, counting all forms. One case in three of the whole series

either died with or showed an active form of tuberculosis, whereas about two cases in five of our chosen "non-organic" series showed similar active tuberculosis.

Whereas it has never perhaps been convincingly shown that active tuberculosis outside the nervous system can produce important non-exudative lesions within the nervous system, it is probably a sound policy to exclude such cases from a list *sans reproche*, especially if intracellular conditions are to be studied. This process would leave us with *23 cases free from coarse destructive brain lesions and from active tuberculosis.*

Nine cases showing *decubitus*, 10 cases of "soft brain" (only one of which occurred in the non-organic series), and 3 cases of *edema of brain substance* might also offer obstacles to finer cytological analysis. For this purpose a list of 21 cases is available, but clinical doubts and difficulties remove 8 cases, leaving 13 cytologically appropriate cases (840, 884, 891, 944, 1006 [typhoid fever], 1034, 1081, 1298, 1303, 1317 [carcinomatosis], 1350, 1358, 1360).

To sum up, we have divided our cases upon anatomical grounds into three groups, (1) cases complicated by gross destructive brain lesions (40%), (2) cases having certain minor anomalies or mildly destructive or irritative lesions (31%), and (3) cases without observed gross lesions (29%). After excluding cases unsuitable for analysis on various grounds, we obtained a group of 29 cases, 15 of which (52%) showed the minor anomalies and mild lesions just mentioned. It will be the task of the next section to study these 15 cases intensively to see whether they evince any common features. Later studies may then apply these observations to the rest of the series, in which significant lesions may well occur hidden among complications.

IV. CLINICAL AND ANATOMICAL ANALYSIS OF FIFTEEN CASES OF DEMENTIA PRECOX SELECTED AS SHOWING CERTAIN MINOR GROSS LESIONS OF THE NERVOUS SYSTEM.

At this point it seems pertinent to inquire whether, upon a closer analysis of the cases which show minor gross lesions or anomalies, any hint of correlation between these lesions and individual clinical phenomena can be detected. It must be pointed out forthwith that no very close correlation can be hoped for, since we deal with far less constant phenomena than, e. g., those of epilepsy. The histories presented below in as condensed form as deemed advisable to offer a sound basis for clinical diagnosis obviously betray far greater variations in course and qualitatively more complex features than would a similar number of histories of epileptics. But clinical and anatomical correlations even in epilepsy are difficult, despite the firm establishment of the "uncinate" group on an anatomical basis. In view of the clinical variety of the dementia precox group, or even of the group of cases characterized by katatonic symptoms, it is at the outset doubtful whether a "frontal lobe group," a "post-central group," a "cerebellar group" can be firmly established for dementia precox. Obviously such a group should be earnestly essayed.

The *condensed histories*, drawn from the records of numerous workers, among whom may be mentioned Drs. H. W. Mitchell, H. A. Cotton, H. M. Swift and Charles Ricksher, who have been at the heads of services during the major part of the time covered by these reports, and the *summarized autopsy protocols* (for which the pathologists, bacteriologists and assistant physicians named below have been responsible) are here presented.

Case I. S. M., Danvers State Hospital No. 11211, Path. No. 840. Female, thirty-seven, single, school teacher. Born in Cambridge, Mass., of Irish parentage. Was a case of dementia precox, katatonic type, of three years' duration.

Heredity: Negative.

Previous history: Patient taught school from twenty-two to thirty-five. In August, 1901, after a period of overwork, the patient became depressed ("had lost her soul"); her mind dwelt on suicide. Patient remained unoccupied; two weeks after onset of depression was committed to McLean Hospital, where she showed languor, slow in movements, little spontaneous talk, a general effect of emotional gloom and certain somatic delusions ("bowels gone"). A brief attack of excitement followed, with confusion and resistiveness. Short periods of excitement followed with later increasing inertia and little spontaneous talk. Seven weeks after commitment she began to show increase of muscular tension and had to be tube-fed.

Patient was transferred to Danvers Hospital April 1, 1903, and then showed a flushed face, clammy skin and considerable acne. Pulse slow and weak, respirations shallow.

The katatonic signs consisted of an evenly distributed increase of muscular tension. Patient lay constantly in bed, on one side, with arms loosely adducted, hands clenched, legs flexed, chin and knees drawn together, eyelids tightly closed, a fixed facial expression, with lips protruded.

At first patient would take food from a cup, but tube-feeding was later constantly resorted to.

Patient would flinch slightly to pin pricks, but would not move limb even if pin was deeply thrust. Risus sardonicus appeared at times. Occasionally, the eyelids were kept half closed and the eyeballs rolled upward.

Within six weeks a slight physical failure was noted. Patient would occasionally speak at night. Later, talking spells occasionally appeared, such as "Go away," "Stop that. Oh, what shall I do? I can't read. Oh, a thousand times. It is nothing at all," or again "I shall have to stop in this bed forever. God Almighty in heaven, here I am talking, and I have no head. I am as empty as space. There is nothing in this bed, and I have no head. I have fixed everything wrong. It is terrible. Look, I am talking without a head. It is impossible. Is it not? An empty bed. I am a skeleton bitch. This is a frightful impossibility." (Looking at her hands she said,) "These are not hands. How can I do this talking without a head? God help me. It is all wrong. I simply imagine that I see them. There is nobody here, the bed is empty. I don't know what I am doing."

Emaciation became rapid late in 1903, and patient died after a period of continued fever.

Anatomical Diagnosis. (A. M. Barrett.) — *Cause of death:* Phthisis pulmonalis.

Chronic conditions: Poor musculature, malnutrition, bilateral chronic adhesive (apical and posterior) pleuritis, tuberculous cavity of apex of left lung, cavitation and disseminated tuberculosis of upper lobes of both lungs, enlarged bronchial lymph nodes, bronchitis, chronic fibrous ("milk patch") pericarditis.

Recent conditions: (Possibly bronchitis and bronchial lymphnoditis), fatty liver (microscopic evidence), fatty kidney (microscopic evidence slight).

Nervous system: Brain weight, 1090 gm.; generalized increase of consistence of brain, slight visible atrophy of gyri of both frontal regions, cerebral cortex unusually dark in color, but without puncta cruenta.

CASE II. P. F., Danvers State Hospital No. 10147, Path. No. 991. Male, thirty-five, married, carpenter. Born in Nova Scotia, of Nova Scotian parents. Was a case of dementia precox, paranoid type.

Heredity: Negative.

Previous history: Masturbation, sexual excess. At twenty-one years, married, five children. At thirty-one years, "nervousness," loss of confidence, somatopsychic delusions ("heart gone," "insides working"). In hospital quiet, apathetic, hypochrondriacal. Discharged at thirty-five and next year recommitted. Diagnosis, hypochrondriacal paranoia. The diagnosis was later changed to chronic melancholia. Emaciation and suspicion of phthisis at thirty-eight years. Signs of phthisis upon recommitment at Danvers State Hospital, Oct. 25, 1902. Extremities blue, teeth poor. At first refused food. Groaning and complaints of pain and abnormal sensations. Disorientation (lack of interest) for time and place.

"I can't speak because it pulls down and pulls up, and is wound around me." At no time katatonic signs, except mutism (possibly paranoidal origin).

ANATOMICAL DIAGNOSIS (A. M. Barrett.) — *Cause of death:* Phthisis pulmonalis.

Chronic condition: Malnutrition, poor musculature, chronic obliterative pleuritis, bilateral, phthisis pulmonalis with cavitation and fibrosis, chronic perisplenitis chronic interstitial nephritis, exostosis on inner surface of frontal bone, adherent dura.

Acute condition: Acute fibrinous pericarditis (organism of colon group).

Nervous system: Brain weight, 1360 gm.; slight generalized cerebral gliosis.

CASE III. R. O., Danvers State Hospital No. 11871, 12756, Path. No. 1034. Male, thirty-five, single, shoe factory operative. Born in Italy. Was a case of dementia precox, at first paranoid, later katatonic, of two years' duration.

Facts concerning *heredity* unknown.

Previous history: Emigrated from Italy at about twenty-three. Shoe factory operative of average capacity. Easily affected by alcohol (some beer and whiskey daily). In March, 1904, stated that anarchists and socialists wished to kill him; that he heard men talking and singing in the next room; thought that people were going to "do him," and ceased to work steadily. In the course of five or six weeks patient began to feel that his friends had turned against him, and when a man borrowed his mandolin and returned it minus one string, patient reasoned that he was being hypnotized. At that time, the diagnosis lay between dementia precox and alcoholic insanity, the former preferred.

Patient was committed to Danvers Hospital April 27, 1904. Undersized, unusually hirsute. There was slight swaying in the Romberg position. The knee jerks were exaggerated. Patient was reticent. At one time said, "There is going to be something this side and then on the other side," making signs with his fingers around his head. Once asked to play cards, snatched the cards from the table and refused to give them up. Dulness and inactivity increased, with a tendency to stupor, interspersed with brighter intervals. Nine months after admission, periods with marked echepraxia and some cerea flexibilitas with diminished response to peripheral stimuli set in. Patient became reluctant to eat.

Discharged Feb. 2, 1905, to go to Italy. Patient was readmitted Oct. 5, 1905, with mutism, cerea flexibilitas, slight resistiveness on being roused, fixed facial expression, staring eyes and pouting lips. Slight albuminuria was now demonstrated for the first time. Automatism shortly developed, with prompt obedience to commands, such as protrusion of the tongue for incision. Patient habitually sat for hours with hands spread over knees, staring at the floor. Saliva was held in mouth for hours. Symptoms of pulmonary gangrene set in and patient died a week later, Jan. 23, 1906.

ANATOMICAL DIAGNOSIS. (E. E. Southard.) — *Cause of death:* Gangrene of right lung.

Chronic conditions: Emaciation, unequal pupils, irregularity of right pupil (iris narrow above), slight mitral valvular sclerosis, small heart (150 gm., but left ventricle 1.5 cm. thick) and small aorta (5 cm. in circumference).

Acute conditions: Gangrene of posterior portion of right upper lobe of lung (culture, streptococcus pyogenes and diphtheroid organisms), with acute fibrinous pleuritis, bronchial edema and swelling of bronchial lymph nodes, septicemia (determined on culture, streptococcus pyogenes and diphtheroid organisms).

Unusual hirsuteness.

Nervous system: Brain weight, 1,410 gm.; dentate nuclei abnormally firm and yellowish.

CASE IV. D. R., Danvers State Hospital No. 7987, Path. No. 1062. Female, thirty-eight, married. Born in Nova Scotia, of Irish parentage. Was a case of dementia precox, paranoid type, of eleven years' duration.

Facts of *heredity* unknown.

Previous history: At the age of twenty-eight, about a month before commitment to Danvers State Hospital, patient had been depressed and suicidal, with delusions that she was being killed, had been partially buried, had seen spirits, had had two hearts and was immortal. It appeared that the patient had been lately deserted by her husband and much overworked. She had had three children, one living.

Shortly after admission, Aug. 31, 1895, she was given the diagnosis of primary delusional insanity. She showed râles in both apices and edema of ankles. Patient worked in the laundry. Was occasionally reticent, but at other times freely stated her delusions. Toothaches and neuralgic pains she attributed to external influences. Was at times abusive, noisy and obscene. At other times would show no evidence of mental disorder for several weeks. In the course of two or three years, physical inertia increased, delusions could be still elicited, with somewhat less coherent explanations. Sample of conversation: "I was referring if you thought I felt well and if it was for your purpose to ask these questions. I proved it whether I am worthy of my home. There are two police stations, and if you are acquainted with medical things you will see the church about me." Active auditory hallucinations appeared at times. The tuberculosis probable at admission became definite ten years later. Patient died after a terminal disease of about four months. This patient apparently never showed well-defined katatonic signs, unless occasional reticence with physicians and a single period of mutism can be so interpreted.

Anatomical Diagnosis. (E. E. Southard.) — *Cause of death:* Phthisis pulmonalis.

Chronic conditions: Poor musculature, malnutrition, poor teeth, linear atrophiæ of abdominal skin, chronic obliterative pleuritis (right) and extensive adhesions of left pleura, extensive bilateral tuberculosis with cavitation of lungs and bronchitis, enlargement and induration of bronchial lymph nodes (tuberculosis microscopically), aortic, common iliac, internal iliac (slight), renal (microscopic) and (slight) coronary arteriosclerosis, fatty liver with (microscopically) slight portal cirrhosis, genitalia atrophic, thyroid small (aberrant thyroid above bifurcation of trachea, right anterior, 2 by 1.5 by 0.5 cm.), marrow of right femur red.

Nervous system: Brain weight, 1,260 gm.; gliosis of superior frontal, prefrontal and orbital gyri; brain (except gliotic areas and occipital gyri) and spinal cord (especially lumbar) reduced in consistence; cerebellar cortex darker than cerebral cortex.

Case V. M. R., Danvers State Hospital No. 6531, Path. No. 1137. Male, thirty-five, single, shoe factory operative. Born in Lynn, Mass., of Irish parentage. Was a case of dementia precox, at first paranoid, later at times katatonic and finally demented of about fifteen years' total duration.

Heredity of insanity denied. Father possibly alcoholic. A brother died of tuberculosis.

Previous history: Sept. 1, 1891, patient developed a delusion that persons in an electric-light plant opposite his shop were putting currents on him. Insomnia, constipation, lack of appetite, pains in the head and confusion of mind followed, and patient was committed to Danvers State Hospital, Oct. 2, 1891, with exaggerated knee jerks and little or no physical disorder. Apparent dementia increased. Unusual motions and gestures could not be explained by patient. At first he worked well in the brush shop, but later ceased work, became mute and sat still in one place, smiling. The attendant could get patient to walk up and down the ward. Limbs were habitually blue and cold. In taking exercise, a certain number of steps were always taken and a certain crack in the floor was followed. When seated, the limbs were held fixed and the mouth open. At times the patient would sit gesticulating for long periods at a time. Later, the gestures and peculiar attitudes ceased, but mutism persisted. Once, in 1903, the patient whispered a few words. There was never any refusal of food during the Danvers stay. Death Jan. 19, 1906.

Anatomical Diagnosis. (E. E. Southard.) — *Cause of death:* Phthisis pulmonalis.

Chronic conditions: Malnutrition, chronic adhesive pleuritis of left upper lobe and right apex, mitral valvular sclerosis, brown atrophy of heart muscle, small heart (170 gm., but left ventricle 1.3 cm. thick) and small aorta, chronic interstitial nephritis, dilatation of stomach, right testis fibrotic.

Recent conditions: Tuberculous pneumonia of left lung, with acute fibrinous pleuritis, bronchopneumonia of posterior portion of right lung, early enterocolitis (?) with large, soft mesenteric lymph nodes, acute splenitis fatty liver and kidney (both slight).

Nervous system: Brain weight, 1,465 gm.; superficial asymmetry in minor sulci of cerebrum, microgyria of right superior parietal lobule (no certain evidence of atrophy, but more flaring sulci; in particular the right parieto-occipital fissure is 1 cm. deeper and much wider than the left), focal chronic fibrous leptomeningitis of right parieto-occipital fissure, consistence of brain diminished (anterior poles least, and lower surface of cerebellum less than upper surface).

Chemistry: The water-content of three portions of the brain was determined in the chemical laboratory of the Harvard Medical School by Mr. J. B. Ayer, Jr., who found the following percentages: Frontal region, 75% water; parietal, 77%; cerebellum, 82% water. These findings parallel the consistence noted with the finger. The anterior poles were the least softened. The low percentage of water possibly indicates relatively high neuroglia content.

Case VI. G. B., Danvers State Hospital No. 11641, 3238, Path. No. 1149. Male, fifty-seven, single, carpenter. Born in Salem, Mass., of American stock. Was a case of dementia precox, paranoid type, of perhaps thirty-two years' duration.

Heredity: Facts not known.

Previous history: Was perhaps not "just right" from boyhood. Had certain delusions and may possibly have been suicidal early in life, but was shortly transferred after his first stay at Danvers to the Salem Almshouse, where he was quiet and industrious. Patient showed insomnia at times and had sensations of "sparks of fire" dropping on his head.

Readmitted Jan. 1, 1904, with signs suggesting tuberculosis at both apices. A coarse tremor of extended tongue, a moderately fine tremor of extended fingers and markedly exaggerated knee jerks. Examination by Dr. H. W. Mitchell showed that the knee jerks are usually followed by momentary clonus or tonic spasm of the leg, followed by general body spasm, which does not seem to be always the same. The different movements depend upon the different postures of the body at the time the knee jerk is obtained. Often the same body spasm can be gotten by a feint to strike the quadriceps tendon. Achilles reflex is prompt, but not much increased. It is followed, however, by various spasms of the legs, the most common being a tonic spasm of the muscles of the leg and thigh, often accompanied by irregular spasms of muscles of the trunk. *Triceps* and *biceps* prompt and lively and followed by irregular body spasms. *Cremasteric* and abdominal slight. *Plantar* very much increased, followed by tonic or clonic leg spasms. Usually no lifting of right toe. Rarely a suggestion of Babinsky reflex. The only physical stigma consisted in poorly formed lobules.

Auditory hallucinations had been frequent for many years, always in the tones of attendants or other bystanders. There was one episode of visual, olfactory and gustatory hallucinations of an unpleasant character.

Very characteristic were patient's description of peculiar spiritualistic phenomena, with "forerunners and communications." Patient would often communicate with God, assuming a rigid position, gazing into space, and saying, "God, our Heavenly Father, I would like to communicate, if convenient, don't discommode yourself?" He pauses a few moments and then says, "Is that you? Is that you really, Heavenly Father? Please come as an apparition, as strong as you can"; then in a faint voice, "That's pretty good, pretty good. Can you come a little stronger, I wish you would if you could; that's pretty good, that's good. God, Heavenly Father, is it safe to show the forerunner in the face of Dr. Mitchell? Are you sure, perfectly sure? All right." He would then make a peculiar movement of the hands which he alleges is a forerunner and has the power of destroying life. Asked to forecast the future, he calls up God as previously and says, "I wish to ask a question in regard to Dr. Mitchell's success in the future? Is your time precious, God? Can you spare it?" He turns to examiner and says, "He is gone now to examine. He examines by astronomy." In the meantime, patient converses pleasantly about the weather until God calls, and later assures examiner that his success is to be unlimited and that he has received

communication. Result of these communications was, as a rule, optimistic.

Patient made characteristic, elaborate, decorative drawings, ostensibly for certain Masonic lodges. In 1905 certain slight mannerisms appeared, which later grew more frequent. He would wet his hands frequently, repeat certain muscular movements, shake his body and make peculiar noises in his throat.

The patient died March 1, 1907, having been taken the day previously with vomiting and severe abdominal pains.

ANATOMICAL DIAGNOSIS. (H. W. Mitchell and F. P. Gay.) — *Cause of death:* Tuberculous enterocolitis with ulceration and perforation with localized peritonitis (bacillus coli communis in heart's blood at autopsy.)

Chronic conditions: Emaciation, chronic fibrous pericarditis, slight tricuspid valvular sclerosis, chronic obliterative pleuritis (left) and chronic apical adhesive pleuritis (right), disseminated tuberculosis of both lungs, caseating mesenteric lymph nodes, chronic pericholecystitis, hepatic atrophy (especially left half of right lobe and all of left lobe), chronic splenitis (marked).

Acute conditions (see Cause of Death): Acute nephritis.

Nervous system: Brain weight, 1,490 gm.; generalized cerebral sclerosis (without visible atrophy), occipital lobes firmer than rest of brain, chronic fibrous leptomeningitis confined to the superior frontal gyri, cerebellum and spinal cord soft, slight chronic external adhesive pachymeningitis.

CASE VII. R. B., Danvers State Hospital No. 11863, Path. No. 1168. Female, twenty-four, single, a weaver by occupation. Born in Canada, of French-Canadian parentage. Was a case of dementia precox, hebephrenic type, of four years' duration.

Heredity: An aunt insane.

Previous history: Of normal early developement. Four years a weaver in Massachusetts. Deserted by lover at twenty. Indifference and melancholy, auditory hallucinations, delusions of persecution, subjective sensations of heat. Occasional attacks of violence and refusal to be dressed followed.

Upon commitment, April 22, 1904, a slight tremor of tongue, slight albuminuria and semi-adherent lobules were noted. Patient was quiet, usually mute, indifferent, occasionally irritable and resistive. Patient lay in bed with clothes pulled over her head and would start up suddenly, rocking back and forth.

There was an apparent amnesia for recent and remote events. Auditory hallucinations, ill-defined delusions of persecution, a silly apathetic attitude persisted. Mutism developed later.

About a year after admission, signs of tuberculosis and physical failure set in, and seventeen months after admission, signs of tuberculosis were detected and tubercle bacilli were found. Thereafter patient grew brighter and would occasionally sing, but would not talk and had to be tube-fed. The knee jerks, normal on admission, were later lost (September, 1906).

The patient died May 4, 1907, about fourteen months after onset of physical failure.

ANATOMICAL DIAGNOSIS. (E. E. Southard.) — *Cause of death:* Thrombosis of left common iliac vein and vena cava (unidentified organisms).

Chronic conditions: Malnutrition, ascites, hypertrophic cirrhosis of liver (2,260 gm.), chronic adhesive pleuritis (both upper lobes), bilateral phthisis pulmonalis, bronchial lymph node tuberculosis, brown atrophy of heart muscle, slight mitral valvular sclerosis, coronary arteriosclerosis, chronic gastritis, slight enlargement of right lobe of thyroid gland.

Recent conditions (see Cause of Death): Edema of left leg, fatty changes in liver and kidney, acute perisplenitis (extension from pleural process).

Nervous system: Brain weight, 1,105 gm. The cerebral hemispheres show no variety in consistence and suggest a slight softening of post-mortem origin. The convolutions are everywhere of the usual richness and appearance, except that the upper two thirds of the post-central gyri appear narrower than normal, being scarce two thirds the width of the precentral gyri. It is impossible to make out on section that the underlying white matter is firmer in the post-central than in the precentral gyri. The limits of this lesion cannot be made out exactly, and the lesion probably represents an anomaly of the post-central gyri. Basal ganglia not remarkable. Weight of cerebellum, bulb and pons, 145 gm. The olives have the consistence of those of a normal brain. The right dentate nucleus is firmer than usual. There is a suggestion of thinning out of the laminæ in the clival and cacuminal regions.

Middle ears: Normal.

Spinal cord: Shows an increase of consistence in the lumbar region, and several segments at various points seem to show a thinning-out of the anterior halves, without, however, demonstrable diminution in the area of cross section.

CASE VIII. J. O., Danvers State Hospital No. 10862, Path. No. 1294. Female, thirty-seven, married, housewife. Born in Lynn, Mass., of Irish parentage. Was a case of mental disease, possibly dementia precox, paranoid type, of six year's duration.

Heredity: Facts not known.

Previous history: Patient was married at twenty-three and had four children, three girls and a boy. Nineteen days after the birth of the last child, which took place normally, except that both legs had been swollen, patient became noisy, thought she was dying and asked for the priest. She was carried to the Lynn Hospital and was there excited and had auditory hallucinations. The left leg had swollen much worse ten days after birth of child.

Upon commitment to Danvers State Hospital, June 5, 1902, this leg was still swollen and the skin scaling. The patient was confused and suspicious, at first tractable, later resistant, occasionally listening to imaginary voices, stating "they seem to speak from my head." Delusions were sometimes somatic. When asked what was the trouble with her, "It is like little bits of formed children. It makes me nervous." Pointing to physician's notebook, she said, "That is not saints' work." Periods of violence with biting, kicking and scratching would alternate with quiet and agreeable periods. Food was refused. Ten days later the patient had become somewhat better and developed some insight, and about a month after admission was apparently recovered from hallucinations. Removed upon a visit by her husband, the patient again became depressed, apprehensive and confused. Heard "rappings" at night. Patient stated, "These things I am telling you are all lies, but I have got to say them, because I have that feeling and cannot explain. I feel as though some one was compelling me to go through with it. This person has a grudge against me." There was considerable variation in the development of hallucinations. Patient spoke of queer doings going on at the hospital and talked about seeing "four generations" walking out of the dining-room. Exceedingly active hallucinations developed again in November, 1902, and patient broke glass to reach her husband, who was being crucified. Patient became resistive, violent, profane, would then relapse into depression and confusion. Food was refused as unnecessary. In February, 1903, patient had become dull, would talk little, was occasionally resistive.

March 9, 1903, said, "When the sandbags came on the ward for the old lady with the fracture, the Lord said even the sandbag liked her because she had sandbags at the Lynn Hospital, and she used to go to the beaches too." Occasionally talked in a grandiose way about being St. Johanna. Occasionally struck patients without provocation and would frequently run the length of the ward for no apparent reason. Patient often spoke of herself in the third person and often knelt in an attitude of prayer. While walking, attempted to touch every tree. Patient began to refuse to dress and take care of her room. Conversation became loose and contained many meaningless phrases. "Why did you come here? You hear me and you know my reports as a queen. Yes, I am the Queen of England. I was known as Mrs. Page in the hospital. The carriages and horses are all in my name. Do you deny it, Johnnie? Who do you mean? Nothing now. I have all my money invested. I have my own rights and places up there."

In 1907 the patient was transferred to the tuberculosis ward and there died, Dec. 14, 1908. Toward the close of life, knee jerks had been exaggerated. There was apparent amnesia and only partial orientation could be demonstrated.

Anatomical Diagnosis. (A. H. Peabody and M. M. Canavan.) — *Cause of death:* Phthisis pulmonalis and tuberculous enteritis with ulceration.

Chronic conditions: Malnutrition, slight ascites, hydrothorax and edema of ankles, hydropericardium, slight chronic fibrous endocarditis, chronic obliterative pleuritis (right), chronic apical pleuritis (left), ovarian atrophy, erosion of cervix, tuberculous ulceration of colon, enlarged lymph nodes near cecum and along aorta, cavitation of left upper lobe, disseminated tuberculosis of right lung, enlarged bronchial lymph nodes, calvarium dense, slight chronic external adhesive pachymeningitis.

Acute conditions: Acute nephritis.

Nervous system: Slight chronic leptomeningitis with adhesions at frontal and temporal tips; brain weight, 1,120 gm.; generalised increase of consistence of cerebrum (especially frontal and occipital), pons and cerebellum.

Case IX. J. W., Danvers State Hospital No. 14591, Path. No. 1298. Female, thirty-six, married, housewife. Born in Dracut, Mass., of Irish parentage. Was a case of dementia precox, katatonic type, of about nine months' duration.

Heredity: Negative. One brother and one sister died of tuberculosis.

Previous history: Healthy as child. A good student, disposed to quick temper. Married at twenty-five. Miscarriage at five months, followed by three boys and a girl. Became nervous and run down at thirty-four years.

Present illness: Onset of pain in right side about April 1, 1908. Several weeks later patient dropped her work complaining of "physical incapacity and pain in the chest." Insomnia and brooding followed, and in June patient complained of having tuberculosis, but said she could not get well. After a vacation she began in August to worry more. She was once disposed to jump out of a window, and several times stated that relatives were trying to cut her up. She feared poison in her food. There were spells of looseness of bowels, followed by constipation.

Patient was committed to Danvers State Hospital, Oct. 6, 1908. Partially adherent lobules of ears. Slight hypertrichosis of upper lip. Gothic palate. Teeth in poor condition. Atrophy of breasts. Expansion of right lung less than that of right. Slight resistence on passive movements. Upon admission patient chiefly lay in bed, as a rule with her eyes full of tears, moved very slowly and expressed the idea that every one was trying to hurt her. Patient's emotional reactions were very slight, although stating that deep palpation of the abdomen hurt her. Her expression gave no signs of pain; although describing fear of being hurt, she gave no further evidence of fear. At first appeared depressed and retarded, she later improved. Had a spell of untidiness, became more active, gave irrelevant replies and showed inertia suggesting dementia precox. The diagnosis of manic-depressive insanity, depressed phase, was first made, largely based on retardation in conversation and movements. In the middle of December, 1908, patient again became untidy and sat on floor, showed certain physical failure. Her conversation was limited largely to "I want to go home." Without definite proof of tuberculosis, she was placed in the building for tuberculosis, and there showed restlessness, negativism, a tendency to pulling bedclothes from other patients and untidiness. There were several slight rises of temperature. Jan. 7, 1909, patient had a severe generalised convulsion, after which time she lost weight, became unable to speak and to swallow easily. She mentioned slight headache in the last few days of her life. Death, Jan. 16, 1909.

Anatomical Diagnosis. (M. M. Canavan and C. G. McGaffin.) — *Cause of death:* Ileocolitis with iliac ulceration. Infection of cerebrospinal fluid with organism resembling bacillus of fowl-cholera.

Chronic conditions: Malnutrition, sacral and trochanteric decubitus, teeth poor, gastroptosis, chronic perisplenitis, chronic peri-appendicitis, chronic adhesive apical pleuritis, slight chronic parietal endocarditis, mitral valvular sclerosis, small vegetation of aortic valve, slight aortic sclerosis, tuberculosis of apices, slight cirrhosis of liver with fatty change, chronic purulent cholecystitis, laceration of cervix, chronic external adhesive pachymeningitis over vertex.

Acute conditions: Tumor of left kidney, acute nephritis (pyelonephritis?), acute endocervicitis, thrombus of left internal iliac artery, ulcers of ileum, injection of jejunum, ileum, colon and rectum.

Nervous system: Pia faintly injected and adherent to dura over left middle frontal in an area 1 by 1 cm. in diameter, 16 cm. from tip of pole. Pia is raised from the brain by a clear fluid over the vertex region. Pia slightly cloudy over vessels, but strips from cortex smoothly. Hemispheres equal in size and in general slightly firmer than normal. The left second temporal convolution is more prominent than others of its side or the opposite temporal convolutions. The left precentral gyrus measures, on mesial aspect, 3 cm.; left post-central, 1.5 cm. The right precentral measures, on mesial aspect, 5 cm.; the right post-central, 1 cm. Sulci around right post-central gaping. Cut sections show the post-centrals to have faint and thin gray matter, and their white matter shrinks from the knife. The ventricles are smooth. Ganglia normal. Basal vessels not notable. Sections of the brain show no further gross lesions; brain weight, 1,300 gm.; pons and cerebellum, 190 gm.

Middle ears, Gasserian ganglia and cord not notable.

Case X. M. M., Danvers State Hospital No. 2874, 11624, Path. No. 1303. Female, single, fifty-five, compositor. Born in Peabody, Mass., of American parentage. Was a case of dementia precox, observed in a terminal stage.

Heredity: An uncle insane at Danvers State Hospital.

Previous history: Patient was admitted to Danvers State Hospital with diagnosis of chronic mania (duration six months) June 6, 1883, and was discharged unimproved to Salem Almshouse Aug. 28, 1885. At twenty-nine believed she was a clairvoyant; apparently

had auditory hallucinations. Complained of pains in throat and constantly spitting blood. "Could feel other people's injuries." Excitement on admission, assumption of absurd attitudes and declamation. Disconnection in talk. Made mysterious mention of Masonic signs. More active delusions brought out by menstruation. Her delusions dealt chiefly with injuries brought upon others which she could feel. At Salem Almshouse the dementia advanced. She had a vagrant tendency and was resistive.

Upon second admission to Danvers State Hospital, Jan. 4, 1904, patient showed a heavy growth of hair on chin and upper lip, a narrow, high palate and slight arcus senilis. Exaggerated knee jerks, continuous tremor of lips, slight lingual tremor, inconstant tremor of hands, slight peripheral arteriosclerosis and signs of aortic sclerosis. Mentally, patient talked disconnectedly in answer to questions. Failed to occupy herself in any way, wore an unchanging facial expression. Claimed to have been dead and reborn many times. Persistently stated that she bore another name than her own and showed an apparent defect of memory for both recent and remote impressions. Was unable to make her way about the ward. Sample of conversation: "We don't know whether it is heaven or earth we are sitting in. The house feels such a move. It moved right along this morning like a train. You were marked when you came in." Do you hear voices sometimes? "I hear the occupants of another world." Do you have any thoughts? "When I read books?" Do you read books? "Sometimes I believe I am a baby with all these attacks." What attacks? "The attacks, points and scoops." Are you out of your mind? "You have got to pray to God to get out of this building. My father told me I would be the Lord's wife. He told me to obey my husband and my Lord." How long have you been married? "I can't tell, a number of years. I have been a baby twice since I have been married."

Again, Why were you sent here? "Because I pushed the bed back and a bullet came through the wall. I was chewed and born and clambered and went through shambles." Why were you sent here? "Because there were so many thieves around." What did you do? "I started my nun work and read my Bible in my room, thank God and all God."

Patient at Middleton Colony restless and vagrant. In last few months the patient grew careless of dress and showed mannerisms, stereotyped movements, resistivism and severe Bright's disease. Death Feb. 16, 1909.

ANATOMICAL DIAGNOSIS. (A. H. Peabody and C. G. McGaffin.) — *Cause of death:* Chronic diffuse nephritis and acute bronchitis.

Chronic conditions: Malnutrition, slight sacral decubitus, aortic valvular sclerosis (foci of calcification), slight aortic sclerosis, coronary arteriosclerosis, dilated stomach, chronic diffuse nephritis, chronic perisplenitis, mural and subperitoneal fibromyomata of uterus, atrophy of ovaries, calvarium dense, exostosis of frontal bone, adherent dura, chronic tympanitis auris, calcification in calx cerebri.

Acute conditions: Acute bronchitis, slight enlargement of mesenteric lymph nodes, abrasions of forehead and left hand.

Nervous system: Brain weight, 1,220 gm.; chronic fibrous leptomeningitis of vertex, along sulci at base of brain and over cerebellar cisterna, generalized increase of consistence of brain, pigmentation of cerebral gray matter.

CASE XI. E. F., Danvers State Hospital No. 13582, Path. No. 1310. Female, twenty-eight, single, mill operative. Born at Manchester, N. H., of Scotch-Irish parentage. Was a case of dementia precox, probably of hebephrenic type, possibly originally imbecile. The total duration of the dementia precox features was perhaps four years.

Heredity: Facts unknown. Insanity in family denied.

Previous history: Patient always of subnormal mental capacity. "Peculiar, stupid and ugly." Dull and backward at school. Worked steadily in a mill, but never saved money. Was sullen and cranky. At twenty-four years irritability, indolence, untidiness, aimless wandering and increasing silliness set in. A tendency to gluttony. The police often picked her up on the street at night.

Patient was admitted to Danvers State Hospital April 5, 1907. Adherent ear lobules. High arching palate. Acne eruption. Gait peculiar, at times normal, at times patient swings one foot in front of the other and totters back and forth (mannerism?). Occasionally turns and twists her fingers about in a stereotyped way, touching objects with finger tips. Knee jerks exaggerated. Patient smiled and grinned, was untidy and habitually lay in bed with clothes over her head. Patient mute except on repeated questioning, when an occasional "yes" or "no" can be elicited. Later patient became more tidy and again untidy. Patient was apparently not oriented while in hospital and showed amnesia and defective impressibility.

Developing fever in November, 1908, she was transferred to the tuberculosis building, where she grew weaker and died March 22, 1909.

ANATOMICAL DIAGNOSIS. (C. G. McGaffin and N. B. Burns.) — *Cause of death:* Phthisis pulmonalis.

Chronic conditions: Malnutrition, unequal pupils, asymmetry of thorax, marked mitral sclerosis, hypertrophy of left ventricle, hydropericardium, chronic adhesive pleuritis of anterior portion of left lung, tuberculosis with cavitation of left lung and slightly of right lung, enlarged bronchial lymph nodes, chronic passive congestion of liver, dextroflexion of uterus, thyroid gland small, cyst of left Fallopian tube.

Acute conditions: Thrombosis of left auricle, staphylococcus septicemia.

Nervous system: Gliosis of both frontal regions, atrophy of left postcentral gyrus, left precentral gyrus broader than right; brain weight, 1,300 gm.

CASE XII. M. C., Danvers State Hospital No. 12143, Path. No. 1317. Female, forty-four, single, mill operative. Born in Ireland, father English, mother Irish. Was a case of dementia precox of paranoid type of twenty-one years' standing.

Heredity: Father intemperate.

Previous history: Patient a woman of ordinary mental capacity. Limited education, of melancholy and reserved tendency. Attack began at twenty-three with insomnia and anorexia, followed later by auditory hallucinations, fear, desire to become a nun and wandering tendency.

On admission to Danvers State Hospital, Oct. 25, 1897, the diagnosis of primary dementia was made. Patient was resistive, repeating "O, my God, protect me." Had auditory hallucinations and various delusions, sometimes religious. Mutism, refused to eat, restlessness, later increased stupidity, untidiness and troublesome activity. In 1890 patient was able to work in the laundry, but in 1893 became quarrelsome and violent, often laughed in meaningless fashion and could not be prevailed upon to answer questions. Removed to Lawrence Almshouse June, 1893.

Recommitted to Danvers State Hospital, Aug. 31, 1904. Patient sat about idly, talking to herself or laughing in a silly manner, and if permitted would wear four or five aprons. Her speech was peculiar and

babyish, and many replies were in whispers. Disorientation was apparently complete. Memory for recent and remote events was poorly preserved. Grimaces and various mannerisms. Patient would for long periods sit about listlessly and then become talkative. At times patient became quarrelsome, noisy at night and resistive.

Cancer of left breast was noted in July, 1908. Operation, Nov. 30, 1908, had no effect on mental state. Death from metastases May 19, 1909.

ANATOMICAL DIAGNOSIS. (A. H. Peabody and M. M. Canavan.) — *Cause of death:* Multiple metastatic carcinomatosis.

Chronic conditions: Inequality of pupils, edema ankles, brown atrophy, heart muscle, slight coronary arteriosclerosis, chronic peri-appendicitis, chronic adhesive pleuritis, lateral displacement of uterus, chronic gastritis, surgical removement of left breast (carcinoma), *carcinoma* of axillary lymph nodes, left lungs, bronchial lymph nodes and liver.

Acute conditions: Icterus, hemorrhagic conjunctivitis, hemorrhagic endometritis, acute nephritis, hypostatic pneumonia.

Nervous system: Adherent dura, chronic fibrous leptomeningitis along sulci, occipital microgyria, cervical spinal cord firm; brain weight, 1,210 gm.

CASE XIII. M. K., Danvers State Hospital No. 14597, Path. No. 1319. Female, thirty-one, married, mill operative. Born in Ireland. Was a case of dementia precox of the paranoid type (possibly imbecile) of eight years' duration.

Heredity: Sister epileptic.

Previous history: Poor scholar and truant in convent school in Ireland. Housework and mill work after coming to America at fifteen. Married at eighteen, three children, followed by separation. Illegitimate child at twenty-three. An attempt at suicide is asserted at twenty-three and twenty-four. History before commitment is limited. Insomnia and street-walking are reported.

Commitment to Danvers State Hospital Oct. 10, 1908. Slight coarse tremor of fingers and tongue. Patient dull and apathetic. Lay quietly in bed looking at one point on ceiling as if hallucinated. Orientation imperfect. School knowledge and calculability deficient. Memory somewhat impaired for remote events, still more impaired for recent events. It later transpired that she could see the Virgin Mary at any time. Patient at times sang religious strains. Muscular movements were in general slow and languid. She was apt to assume attitudes suggesting those of saints in religious pictures. Once she betrayed a fear that men were after her. In January, 1909, she had become at times resistive and fearful. She was tube-fed several times. At times patient stated that she had a bad taste in her mouth.

Died May 28, 1909, of colitis.

ANATOMICAL DIAGNOSIS. (A. H. Peabody and M. M. Canavan.) — *Cause of death:* Acute follicular colitis.

Chronic conditions: Malnutrition, inequality of pupils, edema of ankles, ascites, chronic adhesive pleuritis (left), chronic fibrous pericarditis, chronic fibrous endocarditis, aortic sclerosis, tuberculosis of left apex, chronic perisplenitis, renal arteriosclerosis, chronic diffuse nephritis, slight cirrhosis of liver, chronic endocervicitis, calvarium dense.

Acute conditions: Acute nephritis, acute jejunitis, ileitis and colitis, acute proctitis, acute vaginitis.

Nervous system: Cervical spinal cord large, anomaly of superior temporal gyrus, slight chronic leptomeningitis, especially basal; brain weight, 1,250 gm.

CASE XIV. F. O., Danvers State Hospital No. 8471, 13648, Path. No. 1335. Male, thirty-two, single, shoemaker. Born in Lynn, Mass. Father born in Massachusetts, mother born in Nova Scotia. Was a case of dementia precox, katatonic type, of twenty years' duration.

Heredity: Paternal grandfather alcoholic.

Previous history: At twelve years an attack of confusion and more or less unconsciousness lasting two weeks. Pains in back and head at intervals for years. At eighteen years spells of laughter and boisterousness, delusions of being mesmerized, elation and depression in spells, insomnia, threats of violence and suicide.

On commitment to Danvers State Hospital, Oct. 23, 1896, patient was talkative and expressed numerous delusions and pseudoscientific theories. "The moon is the blind eye of some animal. There is a change every thousand years, so that the men of a thousand years ago are now women, and vice versa. The reason why the Egyptians are so small is because he put vitriol into them a thousand years ago, and it is all described in the inscriptions. He has the shoulders of an Egyptian, the head of Napoleon or an Italian, and his limbs are French. We are all being continually acted upon by minerals, herbs, electricity and magnetism, and one person's brain acts directly upon another's."

The physical condition was well maintained. There was a progressive apathy, with occasional noisy spells and unprovoked assaults on patients. In 1898 assigned historic parts to officers — head supervisor was Mrs. Grover Cleveland, superintendent was Napoleon, the pathologist was Daniel Webster, etc. Much profane, obscene and foolish talk.

Later, patient was habitually found mumbling and laughing foolishly on a settee. Eczema of buttocks and scrotum from dribbling of urine. Dysentery in September, 1904. The urine then began to show albumin.

Patient's apathy occasionally gave place to excitement, denudative spells and the expression of extravagant delusions.

Transferred to Foxboro State Hospital, March 5, 1907. Readmitted to Danvers State Hospital, May 10, 1907. Untidy, manneristic, with tendency to hold fixed positions. Placed in tuberculosis building in 1908, where he had spells of noise-making. Diarrhea set in in July, 1909, but there was no blood or mucus in the stools. Toward the close, patient could not keep a straight line in walking. Patient's characteristic position was similar, both lying, standing and walking, and consisted in a curled-up stoop with arms folded over abdomen.

Death suddenly, after a gradual exhaustion, Aug. 21, 1909.

ANATOMICAL DIAGNOSIS. (M. M. Canavan and A. A Hornor.) — *Cause of death:* Phthisis pulmonalis, intestinal obstruction.

Chronic conditions: Malnutrition, dilatation of pupils, oval from above downwards, scaling and pigmentation of skin, chronic focal adhesive peritonitis, chronic adhesive apical pleuritis (left), hydrothorax (right), heart small (145 gm.), slight chronic fibrous endocarditis (left ventricle), tuberculosis of apex of left lung, tuberculosis with cavitation of right lung, liver weight 940 gm., cystitis and prostatitis, slightly adherent dura, chronic tympanitis auris (left).

Acute and recent conditions: Intestinal obstruction, acute jejunitis and ileitis, mesenteric lymphnoditis, acute nephritis.

Nervous system: Spinal cord small, chronic leptomeningitis along sulci of vertex, in Sylvian fissures and at base of brain, thrombi of superior longitudinal and left lateral sinuses.

CASE XV. M. D., Danvers State Hospital No. 10098, 10580, Path. No. 1358. Male, twenty-four,

single, shoemaker. Born in New Brunswick, of Irish-Canadian parentage. Was a case of dementia precox, katatonic type, of ten years' duration.

Heredity: Unknown. Orphan.

Previous history: Two years before commitment, malaria, with refusal to talk (patient's statement). Normal to fifteen years, of average school capacity. Ten days before commitment, patient had spells of crying, jumping, shouting and incoherent talk, with refusal of food for about a week. Patient believed he had appendicitis. Urine was drawn with catheter four or five days before commitment. Headache during two nights before commitment.

Commitment, Danvers State Hospital, Sept. 15, 1900. Nose asymmetrical. Malnutrition. Depression explained by patient as due to lack of sleep, having no mother and lack of appetitie. Patient was dazed and bewildered, refused food, was at times normal, later mute, untidy, resistive. The katatonic symptoms then diminished, and patient could be got to take food. Periods of mutism and fixed attitudes alternated with brighter and more responsive periods. Late in 1900, he had become apathetic but worked in the dining-room; occasionally noisy and mischievous. Tonsillitis in March, 1901. Weight and physique had in general much improved. Active symptoms then almost wholly ceased and patient was discharged April 1, 1901.

After discharge, patient worked well in shoeshop and drove team acceptably to employers. On being taken to learn a trade in Boston, August, 1901, he stayed but two weeks and returned erratic, boastful, profane and threatening and was recommitted Oct. 12, 1901, in approximately perfect physical health.

As a rule surly and profane, patient was sometimes tractable (November, 1901; February to July, 1902; September to January, 1903). Occasionally untidy. Often restless, sleepless and annoying to helpless patients. A second attack of follicular tonsillitis, September, 1902.

April, 1904, confusion, peculiar way of putting on clothes, swaggering about, mutism or incoherent responses to questions, facial grimaces, twitching of facial muscles. November and December, 1904, orderly and tractable, though apathetic, correspondent with an attack somewhat suggestive of typhoid fever (positive Widal reaction in second week).

During 1905 and 1906, patient was apathetic, idle, properly oriented and had very good memory.

In the spring of 1906, patient grew depressed and unwilling to eat, became untidy, mumbling and disoriented, and during July and August became restless, excited, given to running about, making peculiar movements and assaulting helpless patients. A period of dulness followed.

Patient's weight increased, he was given parole privileges.

In February, 1909, patient grew despondent and untidy, often refused food and took to continual praying. In August dysentery set in, with persistent diarrhea, mutism and occasional prayers.

Sudden collapse set in on Nov. 18, 1909. Death. Patient mumbled a few words to physician on day of death.

Anatomical Diagnosis. (H. M. Adler and M. M. Canavan.) — *Cause of death:* Acute ulcerative ileocolitis (bacillary dysentery).

Chronic conditions: Malnutrition, unequal pupils, trochanteric decubitus, chronic appendicitis, chronic obliterative pleuritis (right), obsolete tuberculosis of left apex, chronic perisplenitis, chronic gastritis, cystitis (thickened wall), calcification of lymph node near pancreas, calvarium thick, slightly adherent dura mater.

Acute conditions: Acute ileocolitis, enlargement of mesenteric lymph nodes, acute bronchitis (right), acute splenitis, fatty changes of liver and (slight) kidneys.

Nervous system: Sclerosis of left inferior frontal gyrus; brain weight, 1,200 gm.; slight chronic fibrous leptomeningitis, lumbar spinal cord soft.

In seeking for correlations in these data, let us first inquire how many of the lesions described can safely or probably be regarded as congenital anomalies or lesions acquired long prior to mental change. For a proper judgment here we shall need to take into account not merely the lesions in question, but the total clinical and anatomical impression presented by each case.

I. 840. A woman of Irish extraction, a capable school-teacher for thirteen years, developed at thirty-five, after over-work, a depressed, delusive, languid state, upon which typical katatonic symptoms shortly supervened, and died of phthisis at thirty-seven. Possibly the brain was somewhat atrophied, but not visibly so, save in the frontal regions. Although visible generalized atrophy cannot be asserted, there was a palpable generalized gliosis. (*Acquired.*)

II. 991. A Nova Scotian carpenter, given to frequent masturbation and later to excess in venery, developed a mental disease at twenty-four, variously diagnosed in different state hospitals as "hypochondriacal paranoia," "chronic melancholia," "neurasthenia"; is said to have threatened suicide; complained of pain, abnormal sensations ("brain and legs whirling round," "I can't speak because it pulls down and up and wound around me"— making motions from abdomen to neck); was hypochondriacal, eventually answered only in monosyllables, developed tuberculosis and died at thirty-five. Slight generalized cerebral gliosis without visible atrophy. (*Acquired.*)

III. 1034. An Italian immigrant, for ten years a shoe operative of average capacity, somewhat easily affected by alcohol, developed at thirty-three auditory hallucinations and persecutory delusions, later grew dull, reticent, given to impulsive acts, and then showed echopraxis, cerea flexibilitas, mutism, at times automatism, died of pulmonary gangrene at thirty-five. A kind of simian hirsuteness and hypoplasia of heart and aorta perhaps suggest "degeneracy." The pupils also were unequal and one was oval. The brain of this case was of good weight, and the solitary lesion it showed was a sclerosis and pigmentation of the dentate nuclei of the cerebellum. (*Acquired.*)

IV. 1062. An Irish housewife, who had borne three children, was deserted by her husband and developed at twenty-eight somatic delusions, depression and suicidal tendencies. On commitment signs of tuberculosis of both apices were discovered, which tuberculosis was fatal ten years later. Full of delusions, abusive, noisy, obscene, the woman never showed katatonic signs unless reticence and a single period of mutism can be so interpreted. The brain of this case was of proper weight and showed palpable gliosis (without visible atrophy) of the superior frontal, prefrontal and orbital gyri. At death (thirty-eight years) the genitalia were already atrophic. There was an aberrent thyroid. (*Acquired.*)

V. 1137. An Irish shoe operative (father possibly alcoholic) developed loose delusions of influence and a little later peculiar motions and gestures, mutism, stereotyped movements. All these symptoms, except mutism, ceased in later years. The total process lasted fifteen years and the man died at thirty-five. As in Case II, both heart and aorta were small. One testis was atrophied. The brain weighed 1,465 gm. and

showed a striking microgyria of the right superior parietal lobule. Whether this lesion is acquired or aplastic would be hard to decide on anatomical grounds, but there was a focus of chronic pial change in the adjacent parieto-occipital fissure. There is a suggestion of sclerotic changes in the frontal regions and the lower surface of the cerebellum. (*Acquired? Congenital?*)

VI. 1149. A carpenter, hyperreligious, and given to spiritualism, perhaps never "just right," has episodes of auditory, visual, olfactory and gustatory hallucinations (possibly also tactile), but during a quiet course of thirty-two years eventually settles into habitual, apparently voluntary, "communications" with God. Certain tremors, of doubtful interpretation, partly voluntary, were at one time evident in reflex tests. Characteristic mannerisms were late in appearing (fifty-five) and were then slight. Death at fifty-seven. The brain showed a generalized increase in consistence (without visible atrophy) and especially firm occipital regions. There was no palpable sclerosis of the frontal regions, but there was a regionary chronic leptomeningitis. (*Acquired.*)

VII. 1168. A French-Canadian woman, of normal development and a weaver for four years, after desertion by lover developed auditory hallucinations, persecutory delusions, certain subjective sensations and resistivism; later apathy, mutism and loss of knee-jerks. Death four years after onset, at twenty-four years. The brain weighed 1105 gm. and showed an atrophy (or aplasia) of both post-central gyri, a mild sclerosis of the right dentate nucleus and possibly other slight chronic cerebellar lesions. (*Acquired. Congenital?*)

VIII. 1294. An Irish housewife, who had borne four children, developed swelling of both legs at her fourth confinement and nineteen days after birth of child became boisterous, fearful of death and had auditory hallucinations — thrombosis of left leg had set in. Auditory hallucinations, delusions of suspicion and periods of violence gave place to virtual recovery. At home, recurrence of hallucinations, followed in the hospital by violence, resistiveness, refusal of food; later, apathy. Impulsive movements, frequent genuflexion, employment of third for first person, stereotyped movements. Death after six years, at thirty-seven. Generalized slight cerebral sclerosis, especially frontal and occipital. Slight focal leptomeningitis, frontal poles and tips of temporal lobes. Atrophy of ovaries. (*Acquired.*)

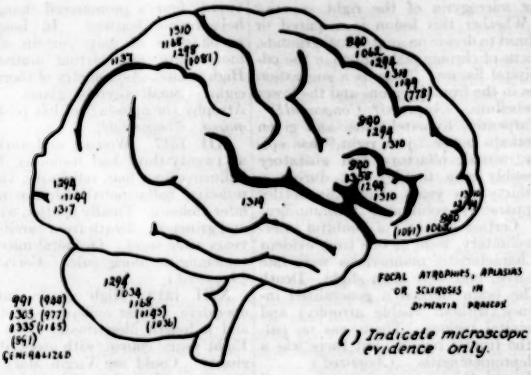
IX. 1298. An Irish housewife, who had borne four children, developed pains, insomnia, ideas of suicide, fear of tuberculosis, delusions of poisoning. On commitment, hypertrichosis of upper lip and atrophy of breasts had set in. The palate was Gothic. The symptoms first suggested the depressed phase of manic-depressive insanity. Apathy, negativism, untidiness followed a severe generalized convulsion nine days before death (nine weeks after onset, thirty-six years). Brain of proper weight. Atrophy (or aplasia?) of post-central gyri. Gliosis of left second temporal gyrus. (*Acquired? Congenital?*)

X. 1303. A woman compositor of New England parentage (uncle insane) believed at twenty-nine that she was clairvoyant and apparently had auditory hallucinations as well as somatopsychic delusions, possibly based on hallucinations. Apathy, peculiar autopsychic delusions toward death, carelessness in dress, mannerisms, sterotypy, resistiveness. Course of twenty-five years. Death at fifty-five. Generalized increase of consistence of brain, with pigmentation and a chronic leptomeningitis of the vertex, along sulci, at the base and over cerebellar cisterna. (*Acquired.*)

XI. 1310. A Scotch-Irish mill-worker, a woman always of subnormal mental capacity, developed at twenty-four a pronounced change of character, with hebephrenic features. In hospital, mannerisms or peculiarities of gait, certain mannerisms of finger movements, and virtual mutism. Unequal pupils. High palate. Asymmetry of thorax. Death at twenty-eight. Small thyroid gland. Frontal lobe gliosis. Atrophy (or aplasia?) of left post-central gyrus. (*Acquired. Congenital?*)

XII. 1317. Woman, mill-worker (father alcoholic), at twenty-three had insomnia, followed by auditory hallucinations, fear, religiosity, vagrancy. In hospital, resistive, hallucinated, delusive, mute, refusing to eat; later violence. Finally apathy, with manneristic speech and grimaces. Death from carcinomatosis, twenty-one years after onset. Occipital microgyria. Chronic leptomeningitis along sulci. Cervical spinal cord firm. (*Acquired.*)

XIII. 1319. High grade imbecile. Irish mill-operative. Sister epileptic. Mother of three children and a fourth illegitimate. One attempt at suicide? Eight years' course, with onset at twenty-three. Religiosity. Could see Virgin Mary at any time (hallucination rather than delusion). Imitation of saints' attitudes as seen in pictures. Possible gustatory hallucinations. Death at thirty-one. Unequal pupils. Superior temporal anomaly. Cervical spinal cord unusually large. Slight leptomeningitis, especially basal. (*Acquired and congenital.*)



XIV. 1335. Shoe operative. Attack of doubtful character at twelve years. Paranoid symptoms began at eighteen. Katatonic symptoms gradually supplanted the paranoid. Death at thirty-two. Spinal cord unusually small. Brain weighed 985 gm., but was apparently not to any great degree atrophied. Heart (145 gm.) and liver (945 gm.) also small. (*Congenital.*)

XV. 1358. Irish-Canadian, shoe-operative. Onset at fifteen. Katatonic, later apathetic, then apparently recovered (seven months after onset). Recurrence four months later. Remarkably periodic course. Death at twenty-four. Palpable sclerosis of the left inferior frontal gyrus. Slight chronic fibrous leptomeningitis. (*Acquired.*)

One's superficial judgment, therefore, concerning the origin of the lesions in question is that they took rise in the adult brain in 840, 991, 1034, 1062, 1149, 1168 (at least in part), 1294, 1303, 1310 (at least in part), 1317, 1319 (in part), 1358 = 12 cases; possibly also in 1137, 1298 = maximum of 14 cases. So far as 1335 is concerned (Case XIV), it might well be doubted whether the hypoplastic nervous system formed more than a nidus for the mental process; perhaps this case should be put in the macroscopically normal group.

It is but fair to insist, on the other hand, upon the congenital features. Besides, 1335, 1137, 1168, 1298, 1310, 1319, gave rise to a suspicion of congenital features in the nervous system alone = 6 cases. And, if we add anatomical features outside the nervous system, then 1034 (hirsuteness, hypoplasia of heart and aorta), 1062 (aberrant thyroid) might be added = a maximum of 8 cases probably or possibly in part provided with congenital features.

It appears, accordingly, that, although congenital features are not absent from our group, there is strong color for the provisional judgment that numerous acquired lesions of the nervous system exist in our series.

The Pre-Rolandic group. The frontal region was specially marked out for injury (whether acquired or congenital is for the moment not considered) in Cases 840, 1062 and 1358; was prominently injured also in 1294 and 1310; and obviously shared to some degree in the generalized mild injury which was macroscopically made out in 991, 1135, 1303 and in 1335 (unless this brain be regarded as showing hypoplasia of congenital origin), i. e., in at most 9 cases.

Consider, first, the three cases in which the macroscopic lesions specially affected the frontal region. Case 840 was at first paranoid, then shortly katatonic; 1062 was paranoid, perhaps never katatonic; 1358 was a katatonic case with remarkable remissions. At first sight it seems hopeless to seek clinical correlations in these cases. But, bearing in mind the conclusions of Campbell and Brodmann concerning the histological differentiation of the so-called frontal region into subdivisions, it is clear that we cannot demand close clinical correlations here.

As a matter of fact, the lesions of 840 (the case with paranoid-katatonic course) involved, so far as eye and finger could determine, the *whole* of both frontal regions, and the whole brain itself showed a generalized increase of consistence. Whatever the relation of the patient's brain disease to her symptoms, there is not the slightest doubt that the patient had been subject to a sclerosing brain disease of mild but generalized character during the last years before death (assigned duration, three years). Microscopically, the gliosis of this case was generalized and not demonstrably severer in the infrastellate layers.

But, though the changes of 840 are too severe and widespread and the symptoms too mixed for correlation, the same is not true of 1062 (paranoid, perhaps never katatonic), a woman of the same age as 840, but with a much longer assigned duration of symptoms (eleven years or more), and with alcoholism clouding the issue; 1062 had maintained proper brain weight and showed gliosis confined (so far as macroscopic examination could determine) to the superior frontal, prefrontal and orbital gyri, i. e., to a continuous area probably containing but two histologically separate cortex-types. It is perfectly true that microscopic examination shows a degree of the same process (gliosis, satellitosis) in other regions, so that here again the brain cannot be freed from the suspicion of a generalized change. Still, both macroscopic and microscopic examinations seem to prove that the superior frontal and prefrontal cortex is subject to the most severe and possibly to the oldest process of injury. It becomes, therefore, at least a working hypothesis for this case to consider the paranoid symptoms as related with lesions in the superior frontal and prefrontal regions.

But what kind of interpretation is left open for the purely katatonic case, 1358? The analysis of this case is still far from complete. The greater part of both frontal regions was, as a matter of fact, wholly spared from macroscopic lesion. Only the left inferior frontal gyrus was affected, presenting an induration of an isolated and distinct, though mild, character in the midst of an otherwise apparently normal brain (slight general leptomeningitis). What relation, if any, this particular lesion bears to the katatonia of this (clinically somewhat unusual) case is impossible to say, but it is certain that the data of 1358 do not controvert in any respect the correlations suspected for 1062 (the practically pure paranoid case) or even for 840 (a clinically more rapidly progressive and mixed case), as the macroscopic distribution of the lesions indicates.

The other frontal lobe cases deserve brief mention. The distribution of the lesions in 1294 is in consonance with the progressive paranoid-to-katatonic character of the disease: the case resembles in some respects 840 (just considered), but its duration is longer (six years) and the katatonic symptoms were much delayed in their development. The brain had undergone a mild generalized sclerotic process (widely distributed gliosis microscopically) which had especially affected the frontal and occipital parts of the brain and included the cerebellar cortex and even the

pons. The frontal tips actually showed a few pial adhesions (a rare event outside of general paresis and other exudative or post-exudative lesions). The extent of this prefrontal process again recalls 840, but the whole case is obviously too complex, progressive and long-standing to permit more than a suspicion of the course of cortical events.

Case 1310 is best considered below among complications of the post-Rolandic group; it showed both delusions and katatonic symptoms, but was at first pronouncedly hebephrenic.

The group of generalized glioses (without defined gross atrophy) here considered numbers three. One of these (991) was practically paranoidal throughout its eleven-year course, and, as a matter of fact, microscopically showed a marked superior frontal lobe gliosis (with satellitosis); but the case is clinically not too clear and no deductions need be risked therefrom.

Another generalized gliosis, 1303, was apparently the end-stage of a hebephrenic, with a disease of twenty-five years' duration. Correlations are impossible. Histologically there were marked gliosis and satellitosis, especially of deeper layers.

Case 1335, the last of this group, is very possibly an instance of hypoplasia or of arrested development of the brain. The brain at autopsy weighed but 985 gm. (heart, 140 gm.; liver, 940 gm.). Correlations here also are difficult.

Before dismissing the pre-Rolandic group, 1149 may be considered in this connection. I have placed 1149 provisionally in the post-Rolandic group largely on the basis of the well-defined occipital gliosis, but the brain showed a generalized sclerosis (microscopically marked, with some degree of satellitosis in places). The reason for possibly including it more especially in the frontal group is the occurrence of chronic fibrous leptomeningitis, confined to the superior frontal gyri. The case was clinically a supreme example of a paranoid dementia precox of thirty-two or more years' duration, and with certain katatonic symptoms appearing very late in life.

The above sketch of the features of the pre-Rolandic group leaves us with the suspicion that paranoid cases begin with lesions striking especially the frontal tips and the superior frontal gyri. Cases with katatonia supervening later and with a progressive course of greater duration show involvement of other regions or even of the whole brain.

The Post-Rolandic Group. (*a*) Cases 1137, 1168, 1298 and 1310 (also frontal) form a subgroup which might, perhaps, be termed sensory-perceptual. (*b*) Cases 1149 and 1317 are cases of occipital lesion, 1319 of superior temporal lesion.

(*a*) The post-central-superior-parietal or sensory-perceptual group of cases claim attention as exhibiting lesions in a region doubtless of great importance in interpretation of sensory impulses. All four of the cases were alike in developing katatonic symptoms.

Case 1137 began, it is true, with a delusion, but a peculiar one (electrification), possibly due to sensory misinterpretation; thereafter the patient developed katatonia, demented seriously, and died (fifteen years' duration). The visible atrophy (or aplasia) in the right superior parietal region, accompanied by microgyria and a dense local deposit of fibrous tissue, formed a striking local lesion. At the time of death, however, gliotic changes with satellitosis had become widespread. Purposely I avoid discussing whether the lesion is acquired or congenital and what its pathogenesis may be, since for the time being the topographic distribution of these lesions is the important consideration.

Case 1168 showed at autopsy what looked like a bilateral anomaly — a hypoplasia of both post-central gyri in their upper two thirds. The onset in this woman occurred at twenty after desertion, and katatonic symptoms were admixed with persecutory delusions and subjective heat-sensations almost at the start. The course was katatonic thereafter.

Case 1298 pursued an acute course of katatonic character, with death after nine months. The brain showed, besides double post-central gliosis in the white matter and visible atrophy of the right post-central gyrus, a peculiar focus of duropial adhesions over the left middle frontal gyrus. This case was at one time diagnosed as depressed phase of manic-depressive insanity.

Case 1310 appears clinically to show a marked imbecilic strain. Perhaps the left post-central atrophy and the precentral inequalities are largely of congenital derivation. The frontal gliosis is consistent with the imbecilic or hebephrenic cast of the case. Numerous katatonic features developed.

The sensory-perceptual subgroup, as represented by these cases, shows lesions which lead to the suspicion, if not the proof, of congenital anomalies. Symptomatically these cases have katatonic symptoms in common.

Post-Rolandic group (*b*). Cases 1149 and 1317, as well as 1294 (discussed with the pre-Rolandic cases), belong to an occipital group.

Case 1149 was briefly mentioned in the frontal connection above because the prominence of the frontal region (which could not be differentiated on palpation from the remainder of the sclerotic brain) was emphasized by a local frontal leptomeningitis. In point of fact, the occipital regions were more markedly sclerotic than the rest of the brain. The case might be asserted to present a beautiful instance of anatomo-clinical correlation were we to insist on the relation between the occipital gliosis and the well-defined, constantly recurring, voluntarily executed visual episodes ("communications with God"). Obviously, such a superfine correlation would mean running a good horse too hard. Those "communications" must have involved numerous cortical events outside the occipital region. It seems safe to maintain, however, that, granting some agency exerting a mildly destructive or irritative effect upon the occipital region, a useless mental habit like these "communications" would probably assume a visual coloring. The existence of disease in a

given brain-region may well be conceived to determine the course of events in the intact remainder. The histological examination of this case is incomplete, but I conclude from available sections that the calcarine cortex-type is relatively intact, whereas the common occipital cortex-type exhibits much more marked gliosis and satellitosis. In this early phase of our problem, it seems best to rely upon coarse and well-defined qualitative distinctions rather than the cell-enumerations which later work will demand. I judge from recent comments on cortex-architecture that the occipito-calcarine relations will be the most vulnerable point of attack in this direction.

Case 1294, which has been discussed above, also exhibited similar histologically demonstrable variations in the intensity of lesions in the calcarine and occipital regions (common occipital type more markedly affected in the infrastellate layers). As a matter of fact, however, in 1294 the hallucinations shown were auditory rather than visual (though the patient once broke glass to reach her husband being crucified). The brain showed frontal, cerebellar and pontine gliosis in addition to the occipital. No temporal gliosis was made out macroscopically, but there were foci of leptomeningitis both at temporal and at frontal tips.

Case 1317 again breaks down in anatomo-clinical correlation much as does 1294, since, despite the occipital microgyria, the hallucinations, so far as was made out clinically, were auditory. There were some religious delusions.

With respect to relative developments of paranoidal and katatonic features in this occipital sub-group, it has been pointed out that 1149 was a classical paranoid case with a few katatonic symptoms toward the close of life (thirty-two years' duration). Case 1317 was more doubtful, but probably can be interpreted as mainly paranoidal; katatonic symptoms developed late in a course of twenty-one years. Case 1294 was paranoidal.

If we compare the sensory-perceptual group (*a*), Cases 1137, 1168, 1298 and 1310, with the occipital group (*b*), 1149, 1317, (1294), we cannot but be struck with the predominantly katatonic character of group (*a*).

Infra-Sylvian group. I have provisionally placed but one case, 1319, in this group, a paranoidal case, probably upon an imbecilic basis. There are no striking anatomo-clinical correlations in the case. This group will undoubtedly grow with further experience. Case 1294, e. g., showed focal leptomeningitis of the temporal tips.

Cerebellar group. It is noteworthy that the cases which we procure at autopsy in dementia precox are provided, as a rule, with multiple lesions. This is particularly true in the advanced cases, where interpretation may be difficult by reason of the fact that gliosis has overtaken the brain as a whole. This difficulty reappears in the cerebellar cases.

Case 1034, however, is a macroscopically pure case of sclerosis of the dentate nuclei of the cerebellum. Clinically, 1034 was a classical example *cerea flexibilitas*, in an Italian of thirty-five years, who began with paranoid symptoms (feared anarchists), and in less than six weeks became typically katatonic. Microscopic examination shows in various areas of the brain a gliosis which had escaped palpation in the gross. Some of the areas of intracortical alteration were undoubtedly far too small to attract attention macroscopically. There was a slight satellitosis of the frontal region. The case appeared, then, like many other cases of this series, microscopically not so definite as the data of palpation had indicated.

Case 1168 is a case which has been briefly mentioned in the sensory-perceptual subgroup of the post-Rolandic cases as showing a hypoplasia of both post-central gyri in their upper two thirds. In addition thereto there was a sclerosis of the olives of the right dentate nucleus of the cerebellum and of the cacuminal and clival portions of the cerebellum. This case was classified as hebephrenic, but mutism, resistivism, assumption of fixed attitudes and impulsive rocking movements give rise to the suspicion that katatonic features cannot be excluded. A congenital element is also very possible from both history and brain findings.

A third case, 1143, showing almost the same findings in the brain, has been excluded from the group of typical dementia precox cases, but might be included upon a more liberal interpretation of sumptoms.

Other cases would have to be added to this group on the score of serious microscopic alterations which were made out in the face of protocols to the effect that the cerebella were macroscopically normal. The group is, therefore, actually much larger than the two cases (1034 and 1168) would indicate.

PROVISIONAL GROUPING OF FOURTEEN CASES WITHOUT RECORDED GROSS LESIONS.

I have analyzed in some detail the cases with recorded minor gross lesions and anomalies to the number of 15. There are 14 outstanding cases having a clear clinical title to the diagnosis of dementia precox, but in which no gross lesions were recorded. It is of interest to learn what light a microscopic examination will throw upon these cases, and whether any cases are subject to a tentative topographic grouping.

There are several cases about which there is no doubt that they actually belong in the gross lesion group. Thus 1145 should, perhaps, have been excluded altogether from this study since the protocols were mislaid. Ample block material exists, however, which microscopically shows characteristic satellitosis of the deep cortex layers and a marked gliosis of the dentate nuclei (more marked left than right). This case might well be placed in Table XVII above, as well as in the cerebellar group.

Case 1145, 10705, female, thirty-seven, paranoid, six years; brain weight, 1,185 gm. (pregnancy at origin).

I am sure, also, that, with increasing experience, Case 1036 would have become an accession to the gross list in the cerebellar group. A sketch of this case was presented by the writer in 1907 in his study of the granule layer of the cerebellum.[23]

Case 1036, 11317, male, twenty-eight, hebephrenic, six years cardiorenal, renal six plus years; brain weight, 1175 gm.

Case 778, a paranoid case upon an imbecilic basis, I should desire to place (with some trepidation) in the superior frontal group. The reason for this is that the superior frontal gyri, far more than other regions examined, gave evidence of a sclerotic process; considerable gliosis of the underlying white matter, superficial gliosis of rather focal character, and perhaps a slight generalized gliosis of the whole gyri, with infrastellate satellitosis. That the process was not confined to this region is true, and neuroglia cell mitosis was a curious finding in the right precentral gyrus. The paranoid features had come on two years before death at forty-one in this imbecile. Very possibly the case scarcely belongs with dementia precox as usually conceived, but it seems certain that a similar process has begun in the tissues.

Case 1081, a suicide, can with some confidence be placed in the post-central subgroup, if only by the evidence of the stained sections which demonstrate a marked inequality in the two post-central gyri. After considerable search, a focus of gliosis and satellitosis was found in one of the orbital regions. This case, a good instance of a hebephrenic with onset at eighteen and suicide at forty-five, shows how a minor lesion — anomaly or acquired lesion, it would not be safe to say which — can be overlooked at autopsy. Had not the post-central gyri been sectioned in co-ordinate places, and had not the orbital gyri been sectioned, this brain might well have passed into the "normal" group both macroscopically and microscopically.

Case 1208 is a case described by Ayer and the writer in 1908,[24] in which the gross findings are so altered by the effects of a suicidal attempt and by terminal metastatic brain abscesses that a judgment concerning essential lesions of dementia precox is difficult. The case should perhaps be excluded from the whole series on the ground of complications.

So excluding 1208, we arrive at the judgment that 15 cases in which gross lesions were actually described, together with 4 cases in which (in all conscience and with greater experience) gross lesions should have been observed, our total of gross lesion cases would run to 19 in 28 (the chosen uncomplicated 29 cases minus Case 1208). This result would mean that gross lesions — focal atrophies and aplasias, and a few focal and diffuse glioses without visible atrophy — are found in 68% of a series of typical dementia precox cases, from which have purposely been previously excluded all instances of frank arteriosclerotic and coarsely wasting processes.

It seems strange that such a high percentage of visible and tangible lesions should have escaped attention if this Danvers series is at all typical of dementia precox in general. I am sure that in many laboratories the brains of autopsied cases fail to get intensive study until after long immersion in formaldehyde solution, which obliterates (or by distortion perhaps conceals) minor size-differences in gyri. Moreover, anatomists, familiar with sculpture anomalies of such relatively plastic organs as the liver, kidney and spleen, are inclined to dismiss cerebral anomalies of sculpture as of the same minor order of interest. Again, the careful palpation of the cerebrum and of the cerebellum is not duly practiced in all laboratories, nor are blocks for microscopic examination chosen on the basis of such intensive inspection and palpation of the brain as careful work demands.

Our own experience has shown how difficult it may be to keep one's house in order for intensive work. Eight cases are outstanding in which notes of gross lesions are missing. Of these 8, 4 show in certain regions characteristic gliosis and satellitosis (891, 944, 977, 1165). The other 4 (794, 806, 873, 1006) have so far proved refractory to our efforts to show stratigraphic alterations.

The result is that 24 out of the chosen 28 cases show either gross and microscopic lesions or microscopic lesions alone, i. e., 86%.

V. THE TOPOGRAPHIC IDEA IN THE STUDY OF DEMENTIA PRECOX AND ALLIED CONDITIONS.

The eternal hope of the neuropathologist is the hope of showing visible "changes" in the nervous system in the functional psychoses, and not only *in* them, but *of* them. All insanity, we hear on every hand, is really nothing but brain-disease, and, if our technic were only better, we should be able to point out the particular brain-changes which are responsible for insanity. I was assured by an enthusiastic psychopathologist that these brain changes are actually so certain to exist that we should not waste our time looking for them!

There are reasons which make this equation

Insanity = brain-disease

really erroneous. In the first place, certain psychiatrists to the contrary notwithstanding, modern work has shown that the equation should better read

Insanities = brain-diseases,

and in the particular form

Some insanities = brain-diseases

perhaps we should be inclined to accept at least the spirit of the statement.

Ever since the doctrines of Flourens were overthrown, from the days of Hughlings Jackson and Hitzig down to the era of the topographers (Campbell and Brodmann, for example), it has been known that the brain is a complex of organs. The brain has parts. Yet those authors who assert that

insanities are diseases of the brain are, as a rule, quite silent as to the brain-*parts* involved. The brain as an organ of mental disease is, for these authors, really the old Flourens brain, having interchangeable parts like a liver or a kidney.

The only justification for this view of which I am aware is the sound idea that the brain, although its parts are not homogeneous and interchangeable, still works in a certain integrated, organized way, and, when disorder and disorganized working of brain-elements supervene, then mental diseases appear. Thus Wernicke supposes that

Insanity = disease of the association elements of the brain.

This is a definite advance upon older conceptions, at all events in clearness. I suppose no one doubts the conceivableness of a mental disease based upon such transcortical lesions of association fibers as Wernicke supposes. But few would be so bold as to generalize the transcortical-injury idea to cover the great bulk of mental diseases.

Even in the field of aphasia, one observes with recent writers a tendency to replace the focal-destruction theory with some theory more consonant with modern ideas as to the tremendous breadth and complexity of the cortical areas subtending speech. From the psychological and logical side comes a vigorous plea from Wundt against the fashionable focalizing of the speech functions in specified areas.

Thus a curious situation develops. On the one hand, the topographers, both physiological and histological, are demonstrating more and more the extreme delicacy of subdivision which exists in the brain-cortex as elsewhere in the nervous system, so that one gains the idea that perhaps no parts of the brain are functionally interchangeable save by re-education. On the other hand, logicians and critical workers are calling a halt upon the focalizers and denying some of the most classical and approved localizations. These latter objections are brought with the more force against the localization of a complex function like speech, which savors of the old faculty-psychology and contains a *soupçon* of phrenology.

I believe we should be even more critical concerning the structural foundations of mental disease. Suppose we grant that any mental symptoms you please, e. g., delusions, hallucinations, negativism, *cerea flexibilitas*, have a cerebral origin, is it necessary to suppose likewise a cerebral disease as a basis therefor? Yes, some would reply, a cerebral disease, but not necessarily structural, perhaps functional only. Even the latter escape I should be tempted to forbid.

Consider diabetes mellitus. The glycosuria has in one sense a renal origin. But it would be a mistake to consider diabetes mellitus a renal disease, structural or functional. I believe that the brain permits certain mental symptoms to develop and purveys these symptoms, much as the kidney of a diabetic permits and purveys glycosuria.

Similar considerations hold with respect to the purveying of convulsions by the brain, an account of which I presented in a paper on the mechanism of gliosis in epilepsy. Neither a convulsion nor a katatonic impulsive movement nor the clenched fist of a thug is adequately explained by lesions of the muscles involved, by lesions of the motor nerves or spinal cord, by activities in the pre-central gyrus or even necessarily by any post-Rolandic or pre-Rolandic brain mechanism or combination of mechanisms. Perhaps, indeed, the reason lodges back of the central nervous system; the convulsion might have been a phenomenon of reflex epilepsy due to intestinal worms; even the katatonic movement might conceivably prove a normal and proper reaction to some received stimulus and the thug's brain might have been quite "normal" while engaged in permitting an asocial act for whose source one should seek far afield.

On such grounds it has not seemed certain to me that mental disease is necessarily brain disease or that, were we able to inspect thoroughly all brain-parts, we should necessarily discover "changes" therein in mental disease. Perhaps the thyroid or the pituitary glands might induce mental symptoms without inducing brain "changes" over and above the proper physiological changes going on in any brain-part during the execution of its normal function. We might be forced to look into the thyroid for the cause of some mental diseases just as into the pancreas for that of a diabetes mellitus.

A priori, therefore, it has not seemed to me at all necessary that diseases like manic-depressive insanity or dementia precox (to use Kraepelin's nomenclature) should exhibit, even theoretically, brain changes. One was especially disposed not to conceive brain changes of a universal character, such as the universal liver changes in phosphorous poisoning, as underlying these diseases. No doubt there are instances of such universal brain change, and no doubt mental symptoms occur as a consequence. Hyperpyrexia might serve as an example. General paresis, however, our paradigm in this field, despite the severe and widespread brain changes which characterize it, is still an example of a disease of focal character. From its protean and progressive character, a theoretically similar focality for brain lesions in dementia precox was thought probable. The mild irritative and persistently complex character of many symptoms in dementia precox seemed to argue very mildly destructive or irritative lesions, such that an occasional definite cure or disappearance of a given symptom or set of symptoms could be effected by removal of irritating factors or by advancing destruction of the offending elements.

If these contentions were sound, it became clear that no random block of brain tissue could demonstrate the nature of dementia precox, as a particular block of lung tissue might demonstrate that of pneumonia. Neither would all the cells be equally or peculiarly affected, nor would the cells of certain strata do more than demonstrate the effects of disease in those strata.

But, if the cells or strata of no random block of brain tissue could serve as a test of dementia precox, would not particular and happily chosen blocks, or even ideally possible total brain sections suitable for cytopathology, solve the problem? I suppose all would agree that such work might solve the problems at least of localization and possibly of pathogenesis in dementia precox provided that the disease is really a brain disease.

I therefore began to study all cases of dementia precox accessible to me (the protocols and prepared sections from the Danvers collection made in Professor Barrett's service and my own) to get a general view of the subject. As will be seen, I at first included with type-cases also cases only doubtfully belonging in dementia precox, and these I have excluded from the conclusions of this report, although many exhibited lesions which might well serve, if we were surer of our conditions, to bring the cases back into the group.

The histopathology, although studied in connection with many of the lesions, has been left in the background to avoid involvement in a tangle of discussion concerning intracortical reflex arcs.

CONCLUSIONS.

1. Existent evidence for the organic nature of dementia precox is not wholly convincing, since (*a*) the cytological changes described are found also in cases of toxic deliria and in cases complicated by severe visceral disease, and (*b*) the stratigraphic changes described are found also in certain senile cases without characteristic symptoms of dementia precox.

2. Resort must, therefore, be had to the topographic idea, for the adequate exploitation of which total-brain sections, with cytological exploration of *all* areas, are ideally necessary.

3. Random blocks of brain tissue with demonstration of satellitosis, infrastellate gliosis or disintegration products of cell disorder will throw little light on the mechanism of dementia precox.

4. The data of the functionalists (dissociation, sejunction, intrapsychic ataxia and the like) are of the utmost importance as indicating the essential focality of the pathogenic process and the focal variations in its severity.

5. The curability of certain cases, the remissive character of some cases, the speedy disappearance of particular symptoms, the persistent complexity of reaction in some instances, the absence of characteristic severe projection-system symptoms, all indicate that the process is histopathologically mild and that the focal changes found will be but slightly destructive or even irritative (in the sense of slight injuries readily repaired or compensated for).

6. Grossly destructive lesions of a transcortical character in Wernicke's sense might conceivably effect, e. g., a permanent katatonic complex, and doubtless will be found to do so occasionally; but the protean and progressive character of dementia precox will exclude such transcortical injuries from playing a large part in the pathogenesis.

7. The focal lesions to be sought for will doubtless escape macroscopic notice in many instances since the volume of apparatus engaged in effecting very prominent symptoms is often slight and spread very thin in numerous areas.

8. Studies of the "soft brain" and of gliosis in epilepsy have proved, however, that even comparatively slight degrees of cortical gliosis can often be palpated at autopsy.

9. Palpable glioses of a focal or variable character, combined in numerous instances with visible atrophy and microgyria, have been found in over half the series under examination, cases regarded as clinically above reproach and *not* subject to coarse wasting processes, focal encephalomalacia, cortical arteriosclerosis or diffuse chronic pial changes.

10. The frequent co-existence of several foci of sclerosis or atrophy in the same brain and the microscopic observation of milder degrees of nerve-cell disorder and gliosis in regions without gross lesions tend to the conception that the agent is more general and diffuse in its action than would seem at first sight, so that future research may well demonstrate that certain instances of coarse brain wasting and even of diffuse chronic leptomeningitis belong in the group (microscopic corroboration necessary for assigning values to focal variations).

11. The microscopic examination of the residue of cases in which gross lesions or anomalies were not described shows the same tendency to gliosis and satellitosis in numerous instances, and the same tendency to focal variations from gyrus to gyrus exhibited by the gross lesion group. These findings suggest that the minor gross lesions and anomalies of several cases actually escaped notice (the protocols, though drawn up with a certain system, are by various hands) at autopsy, so that the probable actual proportion of gross lesions is 68%. If microscopic evidence is resorted to, the "organic" proportion in our series rises to 86%.

12. Several groups of cases were classified from the distribution of macroscopic lesions, although the focal purity of these cases can often be brought in question from the results of microscopic examination (infrastellate gliosis and satellitosis in macroscopically "normal" areas).

I. Pre-Rolandic group, including a superior frontal-prefrontal subgroup of paranoidal trend (*cf.*, e. g., Case 1062).

II. Post-Rolandic group, including

(*a*) Postcentral-superior parietal (sensory-perceptual) subgroup in which katatonic features are the common factors (*cf.*, e. g., Case 1298).

(*b*) Occipital subgroup (*cf.*, Case 1149).

III. Infra-sylvian group (too small for clinical correlations).

IV. Cerebellar group (katatonic features).

13. If these data find general confirmation, they will doubtless go far to unify discussion, since mild, variable and progressive intracortical lesions, proceeding at different rates in different parts of the apparatus, and having the peculiar distributions indicated above, would explain ade-

quately some of the contentions of the dissociationists, while remaining not wholly inconsistent with Kraepelinian ideas.

14. The frontal-paranoid correlation is in line with modern physiological ideas, but it must be granted that the occipital and temporal regions, as elaborating important long-distance impulses, may well play a part also in paranoid states.

15. The cerebellar-katatonic correlation is doubtless in line with some contentions of the Wernicke school, and obvious comments might be made in connection with the proprioceptive functions of the cerebellum (Sherrington).

16. The post-central-superior parietal relations to katatonic symptoms are perhaps theoretically the most novel suggestion from the work, but here again the results are not inconsistent with modern physiology.

17. The topographic study of dementia precox brains, both gross and microscopic, is commended as likely to shed new light on the pathogenesis of certain symptoms, notably paranoidal and katatonic symptoms.

IV.

TEN OBSCURE CASES OF MENTAL DISEASE: A CLINICAL AND ANATOMICAL STUDY.

BY L. B. ALFORD, A.B.,

Special Laboratory Interne (1910) at the Danvers State Hospital, Hathorne, Mass.

IN his study of the margin of error in the diagnosis of mental disease, Southard found 10 cases (4%) of a series of 250, specially reported clinically (at Danvers Hospital conferences) and later autopsied, which, unlike the remainder of the series, did not readily fall into accepted clinical groups. As it was thought that a more intensive study of these cases might reveal appropriate diagnoses, the following analysis was undertaken. First, condensed histories and anatomical analyses were drawn up, from which provisional anatomical and clinical diagnoses were made. Secondly, analysis of available microscopic material was made in every case, and provisional diagnoses made therefrom. Thirdly, a comparison of the three provisional — clinical, anatomical and microscopical — diagnoses was made for each case, and on the basis of this comparison a set of probable diagnoses of still greater finality was drawn up.

Owing to the obscure state in which the structural aspect of mental disease still remains, it is obviously impossible from a study of the microscopical brain and gross autopsy findings alone definitely to place a case in a clinical group. A tentative grouping was made of cases with similar morphological findings, and an effort made, first, to place the cases examined in this study in one of these groups, and then more definitely in a clinical group if possible. Four groups were made as follows:

I. Organic group, in which there are prominent blood-vessel changes or well-defined destruction of brain tissue. It includes general paralysis, cerebral syphilis, arteriosclerotic insanity, tumors, trauma, etc.

II. Senile group, in which there is a diffuse destruction of nerve cells without (necessarily) prominent vessel changes, accompanied by either atrophy of convolutions or decrease in brain weight. It may or may not be accompanied by marked visceral disease.

III. A group of which the mental symptoms may be due to toxic and nutritional disturbances. This group includes cases in which the brain shows no changes outside of physiological limits, but where marked visceral disease of such a nature as to produce toxins or disturbances of nutrition is found. It is made up of the infection and exhaustion psychoses, thyrogenous insanity, etc.

IV. Functional group, in which there are no universally accepted findings of note either in the brain or trunk. It includes dementia precox, manic-depressive insanity and the acute intoxication psychoses.

These groups are not entirely satisfactory. The first and second are fairly definite, but the third and fourth are rather loose. It is impossible to say whether a certain combination of lesions would produce sufficient disturbance of nutri-

tion to cause mental symptoms, so all that can be done is to select lesions that must produce some disturbance of nutrition and assume that they were or were not sufficient to cause mental symptoms in the particular case. Unfortunately, this method will not identify the acute toxic and exhaustive psychoses that have no distinct pathology. It also does not exclude the last group, the "functional" diseases, which may be associated with visceral disease. However, the classification was the best that presented itself for the study of a group of mental cases from the morphological side, and the diagnoses are made tentatively, subject to revision when compared with the clinical symptoms.

The cases are presented in the form of condensed clinical summaries and summarized autopsy protocols. The microscopic examinations are by the writer.

Case I. E. N., Path. No. 850. Male, age seventy years, bookkeeper. Admitted to Danvers State Hospital January, 1883; discharged Jan. 14, 1888. Readmitted Dec. 10, 1903; died Feb. 12, 1904.

One sister insane. Father died of consumption. First admission: Had a common school education. Was cheerful; a moderate drinker; used tobacco to excess. Had been a bookkeeper since 1872. Cause of trouble given as overwork and ill-health. Poor health for one year; for two months in Boston City Hospital. Here he had a cough, vertigo, dyspnea on exertion and pulse of 112. Nervous and excitable.

In hospital was depressed, apprehensive, not violent, had delusions. Took nourishment poorly. Believed he set fire to the city of Portland. Apathetic. Physically on admission was poorly nourished; physical and neurological negative. Diagnosis: Delusional insanity. Discharged on a visit, January, 1907, but was soon brought back by friends.

Second admission, December, 1903. Quiet, feeble, rambled in conversation. Orientation good for place, defective for time. Poor knowledge of current events. No delusions or hallucinations; fair insight. Memory fair for remote events, not so good for recent events; impressibility poor. Emotions normal; at times is confused. Diagnosis: Senile dementia.

Physical examination on admission: Emaciated; arcus senilis. Heart regular, first sound rough, radials thickened. Trace of albumin. Very weak. Tremor and twitching of fingers. Reflexes normal. Pupils equal and sluggish. Sensation dulled.

Autopsy by A. M. Barrett: Decubitus, emaciation, miliary tuberculosis of lungs, liver, spleen and umbilicus, with ulceration, chronic adhesive pleuritis, left and right, chronic fibrous myocarditis, milk spot, chronic mitral endocarditis, chronic fibrous peritonitis, arteriosclerosis with calcification of aorta, chronic parenchymatous nephritis, enlargement mesenteric lymph nodes, chronic external adhesive pachymeningitis, arteriosclerosis of small arteries of brain. Brain weight, 1440 gm.

Cause of death: Miliary tuberculosis, senile debility.

No. 850. The cortex picture is that of a senile brain. The nerve cells are atrophic and deeply pigmented and are slightly decreased in number. The glial cells are increased in number in the gray matter and contain pigment. A number of satellite cells surround the larger nerve cells. The blood vessels are moderately sclerotic, with an increased amount of pigment in the adventitia. Although no mention of convolutional atrophy was made in the protocol, the diagnosis of senile dementia is made on the presence of regressive changes in the nerve cells and glia and the cortical arteriosclerosis.

In the protocol, certain visceral lesions are mentioned which must have produced toxic and nutritive disturbances, and which may have had some influence on the mental symptoms. The chronic tuberculosis and chronic nephritis are probably related with the emaciation noted at autopsy. The milk spot, endocarditis, chronic peritonitis and pleuritis may indicate a former acute infection, or even septicemia, which may also have been a factor in causing the mental symptoms.

The first mental trouble, coming on during a period of ill-health and low vitality, is indefinite in nature and can best be explained as due to a disturbance of nutrition acting on a brain with hereditary weaknesses. It seems reasonable to assume that this attack may have been in some way associated with the septicemia mentioned above; at least the mental symptoms cleared up when the physical conditions improved, and for a number of years the patient was probably without mental symptoms. The second mental disturbance was typical of senile dementia and may or may not have had a connection with the first trouble. The toxemia resulting from the tuberculosis could be thought of as helping to produce mental symptoms, since the brain findings are hardly prominent enough to account for great mental disturbance.

Case II. M. P., Path., No. 896. Female, age seventy-five dressmaker. Admitted to Danvers State Hospital Jan. 1, 1904. Died Aug. 12, 1904.

Heredity: Negative. Common school education. Married at the age of twenty-seven; three children, two girls alive, youngest forty-two years old. Husband died thirty-six years ago. Since that time worked at dressmaking. Had articular rheumatism for twenty years. Went to Salem Almshouse twenty years ago. Onset gradual, five years ago. Thought people talked of her, saying she was a murderess and prisoner; calm unless spoken to, when she became excited.

In hospital was quiet, good-natured, talked freely, depressed. Well oriented, fair knowledge of current events. Memory for recent and remote events good. Heard voices talking about her, usually at night, and had delusions of persecution; often cross and irritable. No insight.

Physical examination on admission. Poorly developed, emaciated; skin dry, eyes sunken; joints of hands and feet enlarged. Pupils normal, arcus senilis. Hearing and vision defective. Reflexes normal. Dullness of right apex. Arteries knotty. Pulse 100, weak. Second aortic accentuated. No murmurs.

Autopsy: Seventy-seven hours post-mortem by A. M. Barrett: Bronchopneumonia of both lungs, acute splenitis, chronic diffuse nephritis, chronic passive congestion of liver, milk spot, old scars at apices, enlargement retroperitoneal lymph nodes, sclerosis of basal vessels, chronic leptomeningitis, increased cerebrospinal fluid, unequal pupils. Brain weight, 1180 gm.

Cause of death: Bronchopneumonia.

No. 896. The changes found in the brain are senile in character. The nerve cells show atrophic changes everywhere and are decreased in number to a slight extent. The glial cells are increased focally both in

gray and white matter, and especially so in the subpial region. Many cells contain pigment. The vessels are slightly arteriosclerotic in places. These changes are nowhere prominent, and it is difficult to say whether they are outside the physiological senile limit, especially since no mention of atrophy of convolutions is made in the protocol.

Outside the terminal condition of bronchopneumonia, there is nothing in the gross findings severe enough to have much importance in producing mental symptoms. The only things in the morphology of any importance, then, are the slight senile brain changes, and the diagnosis of a senile condition of a mild degree must be made. The brain weight is low, 1180 gm., and there may have been some atrophy of convolutions that was not recorded.

The diagnosis of senile paranoia was made clinically, and doubtless is correct. Whether the diagnosis can be said to be supported by the morphological findings is an open question. At least there is nothing to disprove it, and the fact that there was little dementia present agrees with the absence of great atrophy of convolutions and the slight changes found in the microscopical picture of the cortex. It must be admitted, however, that these changes are very slight and in another case might not be associated with mental symptoms at all and that the real cause of the mental disturbance is not clearly disclosed in the morphological findings.

Case III. J. M., Path. No 904. Male, age thirty years, hatmaker. Admitted to Danvers State Hospital Nov. 21, 1903; died Sept. 4, 1904.

Previous history not obtained. *Onset* gradual. Used little liquor. Melancholy. Refused to speak; eyes staring and vacant; would not eat or work. Laughed and cried, slept most of time, shunned companions.

In hospital was quiet, stayed in bed, mute. Understood directions pretty well, took nourishment, cheerful, lay in bed quietly for hours. Would not work at one thing for very long. No cerea. Never spoke a word.

Physical examination on admisson. Well-developed, well nourished. Physical and neurological negative.

Autopsy eighteen hours post-mortem by A. M. Barrett. Acute ulcerative ileocolitis, acute valvular endocarditis (aortic mitral), acute lymphadenitis of mesenteric lymph nodes and those of colon, slight hydropericardium, acute proctitis, fatty myocarditis, chronic diffuse nephritis, fatty liver, chronic passive congestion of the liver, chronic leptomeningitis (frontal), granular ependymitis.

Brain weight, 1650 gm.

Cause of death: Ulcerative enterocolitis (dysentery).

No. 904. Nissl sections show marked cell changes of a destructive nature, and an actual decrease in the number of nerve cells. None of the cells contain much pigment. The neuroglia is not remarkable. Satellite cells surround the larger nerve cells. The vessels show pigmentation in places, but are not thickened. Marchi sections show myelin degeneration in the white matter.

Outside the terminal condition, the only gross condition of interest is the chronic diffuse nephritis. The nerve cell changes noted are probably due to the terminal condition. Hence no diagnosis can be made, and the case is placed in the functional group.

Clinically, the diagnosis is obscure because of absence of history and because the patient refused to speak. The mutism without retardation suggests dementia precox, but there were no other signs that would indicate it. Since this diagnosis cannot be either supported or disproved from the morphological picture, it will have to remain in the functional group without being diagnosed more definitely. Manic-depressive insanity is preferred.

Case IV. B. C. S., Path. No. 969. Male, age fifty-eight years, junk dealer. Admitted to Danvers State Hospital Dec. 30, 1904; died April 21, 1905.

Father and mother both lived to old age. No history of insanity given. Born in Massachusetts; was married fifteen and thirty-five years ago; had three children. No illnesses, no alcohol used. Two years ago was operated on at the Massachusetts General Hospital for carcinoma recti and anal fistula. Here was given morphine, which he continued to use after leaving hospital. Had stricture of the urethra and was operated on several months later at the Malden Hospital for pain in the abdomen, and diffuse aneurysm of left common iliac was found. While here had to be restrained with a sheet. No relief from operation. Went to Carney Hospital for another operation, abdominal, which showed nothing; grew worse. Operated on privately for varicocele. Still continued to have much trouble with stomach; vomited and refused to eat. Wife thinks he ate when she was away. Was quiet during the day, but noisy and restless at night. Threatened suicide, but never made an attempt; was destructive.

In hospital lay in bed; seemed to suffer great pain in abdominal regions. Oriented; no speech defects. School knowledge fair. Had no hallucination; memory fairly good; talked of stomach trouble all the time. Complained more when somebody was around. Tidy; restless at night. After some weeks became quieter; also became disorientated. Said he couldn't die.

Physical examination on admission: Poorly developed, poorly nourished, cyanosis of legs. Skin dry. Dulness over both scapulæ. Heart enlarged to left. Brachials slightly thickened. Neurological examination negative. Hemaglobin, 60%; poikilocytosis.

Autopsy ten hours post mortem by A. M. Barrett: Pulmonary hypostasis, emaciation, pulmonary tuberculosis slight, chronic diffuse nephritis, chronic orchitis, scar of penis, chronic fibrous leptomeningitis (frontal, parietal), chronic external adhesive pachymeningitis, soft edematous brain substance.

Brain weight, 1370 gm.

Cause of death: Pulmonary tuberculosis. Marasmus of involutional melancholia.

No. 969. The nerve cells show changes corresponding to the edema changes of Hoch (Dr. Barrett). Cells are not decreased in number. Pigmentation is prominent in all the larger nerve cells. Glia shows regressive changes. Satellitosis is marked in all the cell layers. There is a slight gliosis of the deeper cell layers. Vessels are not changed. Outside the terminal changes, there is not enough upon which to make a diagnosis.

In the autopsy findings there are pulmonary tuberculosis and chronic diffuse nephritis with emaciation, lesions which indicate that toxemia and disturbance of nutrition occurred. With little in the brain to explain the mental condition,

primary importance must be assigned to these changes, so the case is placed in the toxic group.

Clinically, the diagnosis of involutional melancholia was made. From the history one would conclude that disturbances in nutrition played an important part in the causation of the mental symptoms. The various operations, the morphinism and the stomach trouble all indicate such a disturbance, and, since they occurred before any mental symptoms, can be properly regarded as bearing on the mental symptoms. Although these changes were not disclosed at autopsy, they are in line with and confirm the autopsy findings. The brain changes are doubtless due to the disturbance of nutrition, so that this disturbance can perhaps be accepted as the whole cause of the mental trouble.

Case V. M. G., Path. No. 976. Female, age sixty-five years, housewife. Admitted to Danvers State Hospital May 22, 1905; discharged June 7, 1905.

No insanity in family. Parents lived to old age. Education, common school. Left school to work. At twenty-one married a sailor; husband now a letter-carrier. Had three children, all living, youngest thirty-five years. No serious illnesses. Habits good. Trouble came on six months ago when patient worried much over domestic troubles. Had stomach trouble with vomiting, culminating in extreme weakness, for which patient was sent to Salem Hospital, May 12. Also had prolapse of uterus. After being at hospital for two days her conversation became disconnected and she became restless. Auditory hallucinations appeared and she was given opiates to quiet her. Was very restless and noisy and had to be watched constantly. Imagined she was naked. Mistook strange people for her friends. Transferred to Danvers State Hospital. In hospital confused, restless and resistive on admission. Thought children were outside and tried to get to them. Had auditory hallucinations. Soon became quieter, clearer and more communicative, tidy, lacked spontaneity, confused. Memory fairly good for recent (except most recent) and remote events. Easily became tired and confused. At first disoriented, but later orientation improved. Fair knowledge of current events. Attention poor. Later had insight into hallucinations. Temperature went up, and she had a positive diphtheria culture. Again became confused and disoriented. Given antitoxin, but died.

Physical examination on admission: Well developed, poorly nourished, feeble. Skin dry and wrinkled. Arcus senilis, pupils irregular, would not react. Defects of hearing and vision. Reflexes normal. Tremor of tongue and hands. Some inco-ordination. Heart: Systolic murmur. Arteries thick and tortuous. Trace of albumin in urine.

Autopsy fourteen hours post-mortem by A. M. Barrett: Pulmonary hypostasis, hemorrhage into adrenal, endometritis, chronic fibrous pleuritis, localized at apex, chronic fibrous pericarditis, chronic fibrous endocarditis, mitral sclerosis, chronic diffuse nephritis, chronic leptomeningitis (slight), diphtheria bacilli in throat.

Brain weight, 1,110 gm.

Cause of death: Nephritis.

976. Nerve cells show nothing of note. There are regressive changes in the neuroglia, especially in the gray matter, most marked in the subpial region. A moderate number of satellite cells occur in all cell layers. The only vessel change is some increase in the adventitial pigment.

In the autopsy notes are mentioned chronic diffuse nephritis, chronic fibrous endocarditis and pericarditis. Although they may indicate a disturbance of nutrition, with a septicemia, these lesions are naturally not enough to place the case in the toxic group. The brain weight is very low, but no atrophy of convolutions was mentioned in the protocol. The case is provisionally placed in the functional group.

Clinically the case is one of collapse delirium resulting from the stomach trouble and worry. With the improvement of the physical condition in the hospital came an improvement of the mental symptoms, but when the tonsillitis developed, the mental symptoms became worse again. An erroneous idea of the case is gained from the autopsy findings taken alone. Although the nephritis may have played some part in causing mental symptoms, the principal factor, the stomach trouble, was not such as to be demonstrable at autopsy. The case, therefore, can be shifted to the third group.

Case VI. D. M., Path. No. 1013. Male, age fifty-seven years, laborer. Admitted to Danvers State Hospital May 18, 1905; died Oct. 24, 1905.

Uncle and cousins are insane in Ireland. Born in Ireland, came to this country when seventeen. Could read and write a little. Worked as a laborer and watchman in a factory. Married at twenty-seven years, had two children who died, one in infancy and one at ten years (fourteen years ago). Wife an invalid for two years. Used tobacco excessively, but never used alcohol until he became sick. Had not worked for twelve years. Became apprehensive and suspicious, thought people were mesmerizing him, had auditory hallucinations, would sit for hours in one position thinking. Gave himself up to the police because voices told him to kill somebody. Became worse the last year; memory good until a year ago when it failed considerably; was restless at night and confused. Once threatened wife. Had two sinking spells, one five years ago and one last winter, each lasting two weeks.

In hospital was confused, restless and noisy. Memory poor for recent and remote events. Disoriented, heard voices. Contradicted himself and fabricated. Sometimes euphoric, sometimes irritable. Tidy; once was in a stuporous condition for two days, was not rigid or resistive, was very weak. Explained it as a hypnotic state. Talks of the powers and God.

Physical examination on admission: Extremely well developed and well nourished, feeble. Heart negative. Pulse poor in volume and tension. Arteries not thickened; varicocele. Tremor of hands. Unsteady in Romberg position. Reflexes negative. Pupils equal, sluggish and irregular. Localization of sensation is poor and sensation is dulled.

Autopsy four hours post-mortem by L. Hoag: Pyopneumothorax, localized bronchopneumonia going to abscess formation, atelectasis of right lung, emaciation, fibrous pericarditis slight, arteriosclerosis slight, chronic fibrous pleuritis, old scar of left lung, relative insufficiency of tricuspid valve, chronic diffuse nephritis, slight pachymeningitis, chronic sulcal leptomeningitis, subpial edema, gyri narrowed, frontal slightly; atheroma of cerebral vessels.

Cause of death: Bronchopneumonia and abscess of lung, involutional psychosis.

No. 1013. Pyramidal cells show atrophic changes with increase of pigment. Neuroglia shows some activity. Considerable gliosis of white matter of one

frontal region. Neuroglia cells contain pigment. Satellitosis involving single cells excessively, but leaving most of them entirely free. No vessel changes of note. Adventitia contains an increased amount of pigment. These changes suggest only a senile condition. The narrowing of the gyri in the frontal region with the cortex changes point to a senile dementia. This is further confirmed by the finding of senile changes elsewhere, such as emaciation, arteriosclerosis and nephritis.

Clinically the case is undoubtedly one of katatonic dementia precox, with slight deteriorations until one year before admission. After that time the symptoms suggest senile changes. The case could then be considered as a dementia precox complicated in later life by senile deterioration.

The latter condition is shown in the morphology, but there is nothing to indicate dementia precox. The frontal atrophy and gliosis may have been upon a congenital basis, and, if found early in life, would have led to the correct diagnosis. But, occurring as it did in connection with senile changes elsewhere, there is nothing to distinguish it from the identical condition which is often found in senile dementia. This case shows how easily one may be misled in a study of senile dementia by finding lesions which were present before the onset of the mental trouble. The case is transferred to the functional group.

Case VII. R. Mc., Path. No. 1090. Female, age fifty-five years, no occupation. Admitted to Danvers State Hospital March 23, 1904; died Sept. 6, 1906.

Onset gradual. Patient said she was talking to the Lord. Romances, suspicious, afraid of being poisoned, restless and noisy at night. No further previous history obtained.

In hospital talked much, going into detail. Speech normal, orientation good, consciousness clear. School knowledge rather poor. Denied hallucinations; memory defective, better for recent than for remote events. Loquacious, almost a flight of ideas, had no definite delusions, somewhat suspicious. Untidy. Was fault-finding with nurses and physician, contradicted herself, emotional and irritable. Sometimes was troubled with dyspnea, fast pulse, edema and tendency to suppression of urine. Had bronchitis. In August, in one of these spells, had delusions and perhaps had hallucinations. Attacked other patients. Jan. 24, 1906, developed complete paralysis of right side, of gradual onset. Had a motor aphasia. March 6, 1906, "flaccid" paralysis had improved considerably. July 2, 1906: Convulsions, frothed at the mouth, stuporous for a day. Sept. 4, 1906, had a series of convulsions and died.

Physical examination on admission: Well nourished. Eczema of arms and legs, varicose ulcers. Joints enlarged, particularly those of left foot. Bronchitis in both lungs. Heart irregular, second pulmonic reduplicated, also a murmur not definitely located. Arteries thick. Very weak. Hearing and sight impaired. Reflexes normal. Pupils react sluggishly. Urine negative.

Autopsy forty-five hours post-mortem by E. E. Southard: Mural thrombosis of left auricle, early bronchopneumonia of lower left lobe, general arteriosclerosis moderate, chronic fibrous endocarditis, mitral sclerosis, fatty changes of myocardium, hypertrophy of heart, emphysema of lungs, chronic diffuse nephritis, infarct of kidney (?), chronic splenitis, cirrhosis of liver, chronic adhesive pleuritis (left), chronic perisplenitis, diplœ absent, cerebral softening of left cerebrum, semi-ovale and right sagittal ramus (cholesterin crystals), slight subpial hemorrhage in left fossa sylvii, chronic external adhesive pachymenigitis, atrophy (aplasia?) of right flocculus of cerebellum, right purulent otitis media. Cultures: B. coli and B. flavus in heart's blood, B. coli and M. pyogenes aureus in cerebrospinal fluid, B. coli communis and unidentified coccus in thrombus.

Cause of death: Cerebral hemorrhage, arteriosclerosis.

1090. Sections of the right frontal region show decrease of nerve cells of focal character and gliosis of the white matter. In other regions the nerve cells are not notable. Spider cells occur both in the gray and white matter and are very numerous in the subpial region. They contain pigment, especially in the gray matter. Satellitosis is marked. Vessels show no changes outside increase in adventitial pigment. Sections of orbital area show numerous compound granule cells. The findings might suggest a chronic intoxication of such a mild grade that no cell destruction resulted, but enough to stimulate the neuroglia to activity.

In the gross brain were found a cyst of softening of the right frontal region, and signs of hemorrhage in left centrum semi-ovale, which, however, was too recent to cause pyramidal degeneration or cell destruction. These lesions doubtless caused mental symptoms, but probably came subsequent to the first mental symptoms.

Other post-mortem findings are mural thrombosis of left auricle, infarct of kidney (?), chronic fibrous endocarditis, chronic splenitis, chronic pleuritis, cirrhosis of the liver and myocardial changes. B. coli with other bacteria were found in the thrombus, cerebrospinal fluid and heart's blood. The evidences of old infections in various regions and presence of bacteria in several regions post-mortem indicate that in this case there may have been a septicemia of long standing and mild grade. The evidence of septicemia with disturbance of elimination through the kidneys (chronic nephritis) indicate a chronic toxemia of sufficient severity to cause mental symptoms.

Clinically the case was left unclassified and evidently conforms to no clinical type. But the clinical symptoms are not inconsistent with the anatomical diagnosis of chronic toxic condition. The facts that the symptoms improved slightly after coming into the hospital, that they were very slight for a long time, but again increased during the attacks of heart and kidney trouble, show that the mental symptoms are closely allied to the physical condition. They may have been due more to the nephritis than to the septicemia, which may have developed secondarily as a result of the lowered vitality. In any case, there was a chronic intoxication, and it is reasonable to assume that the mental symptoms were due to this.

Case VIII. L. B., Path. No. 1095. Male, age twenty-eight, shoemaker. Admitted to Danvers State Hospital July 10, 1906; died Sept. 17, 1906.

History of intemperance and insanity. Brothers and sisters are healthy. Had a common school education, worked on a farm for three years, then worked at trade of shoemaker. Was good-natured, quiet and seclusive, used liquors moderately. Had diseases of childhood and probably syphilis four years ago. Two years ago

was operated on, probably for bubos; did not feel well after the operation. For the last three weeks before commitment was restless at night. Two days before admission began to sing, read aloud from the Bible and talked of religion, had crying and laughing spells, and was very active; was never violent or threatening.

On admission was restless, laughed and sang; had to be placed in strong room. Orientation rather poor. Admitted auditory and visual hallucinations of angels singing and God speaking; memory was fair, could give history of life. Was untidy and violent, laughed, sang and talked to God; at times mute and resistive and refused to move. Once was found on the floor, rigid, speechless and refused to move. Took nourishment poorly and grew emaciated. Physically on admission well nourished and well developed. Heart and lungs negative. Arteries slightly hardened. Some incoordination of movements. Reflexes normal. Pupils negative. Sensations normal.

Autopsy three hours post-mortem by E. E. Southard: Acute otitis media (left), distention of bladder, edema of brain substance (encephalitis?), chronic fibrous myocarditis, mitral sclerosis, chronic splenitis, slight sclerosis arch of aorta, chronic orchitis (right), chronic external adhesive pachymeningitis, marked arachnoidal villi, gliosis occipital white matter, heterotopia gray matter in occipital region, more marked than in left.

Note: Culture from heart's blood gave M. pyogenes albus; from middle ear, B. coli communis; from cerebrospinal fluid an unidentified coccus.

Cause of death: Septicemia from infection of hand.

1095. The cortex sections show little. The nerve cells are not notable. The glia is not altered except that in some regions there is a slight gliosis of the infrastellate cell layers. Vessels not altered.

In the autopsy findings there is mentioned a gliosis of occipital white matter and heterotopia of gray matter in the occipital region. These brain findings in the absence of disease indicate a congenital disturbance, and, with the gliosis of the infrastellate cell layer, point to dementia precox. The case is placed in the functional group since there is not sufficient evidence to inidcate anything else.

The diagnosis "dementia precox" was made in this case and agrees with the diagnosis from the morphology.

CASE IX. N. P. H., autopsy No. 1204. Male, age fifty-nine, accountant. Admitted to Danvers State Hospital Oct. 14, 1907; died the same day.

History by son: No heredity. Left school at fifteen years to work, conductor and auditor for a railroad, got along well. Married and had three healthy children. Had never used alcohol, used tobacco moderately. Always cheerful, had always been dyspeptic. Otherwise no history of illness.

Onset six months ago, when patient complained of loss of sleep and fatigue, but continued to work until three months ago, when he broke down and had to quit work. Often had difficulty in breathing and a doctor diagnosed Bright's disease. About a month ago motor aphasia came on; one week ago became apprehensive and suspicious, afraid wife was trying to poison him; said she had the "evil eye." Suffered from insomnia continuously. Never had any hallucinations, convulsions or dizzy spells. For the last day or two has been violent and tried to cut his throat with a razor. Patient died the day of admission, and no further records of the case were taken.

Autopsy four hours post-mortem by E. E. Southard, J. B. Ayer, Jr., and E. T. F. Richards: Superficial wound of neck (suicidal), slight edema of legs, bilateral multiple pulmonary thromboses with massive infarctions, thrombosis prostatic venous plexus (source of emboli), aortic sclerosis, ulceration in lumbar region, coronary, renal and pulmonary arteriosclerosis, bilateral hypertrophy of heart, chronic pericarditis (slight), chronic pericarditis (slight), chronic mitral, parietal, aortic endocarditis, chronic obliterative pleuritis (left), chronic splenitis and old infarct of spleen, slight chronic nephritis, chronic appendicitis and peri-appendicitis, chronic peripancreatitis, interstitial pancreatitis, chronic localized external adhesive pachymeningitis, chronic tympanitis (right), calvarium thick.

Brain weight, 1,230 gm.

Cause of death: Multiple thrombosis, nephritis.

No. 1204. Weigert preparations of the cord show prominent pyramidal degeneration on both sides; also suggest a cell degeneration in the upper cervical region. In the cortex there is slight focal atrophy of nerve cells in the superficial layers in the frontal region; also some decrease of cells in the deeper layers in the frontal and precentral regions. The Betz cells are greatly decreased in number. The neuroglia is increased in the subpial region and is pigmented in the gray matter. There is a slight satellitosis of the superficial cell layers, and a most intense satellitosis of the infra-stellate cell layer, particularly in the frontal and precentral regions, producing marked atrophy of the nerve cells; vessels not changed.

In the autopsy findings, besides the terminal condition, there are advanced arteriosclerosis, chronic endocarditis and pericarditis, appendicitis, nephritis and splenitis, conditions which indicate a septicemia at one time which may have influenced the mental symptoms in its acute stages, but which could hardly be thought of as producing chronic disturbances. The cortical changes are those of a senile brain, but the diagnosis of senile dementia cannot be made owing to the absence of vessel sclerosis and atrophy of convolutions. The decrease in number of Betz cells and pronounced infrastellate gliosis and degeneration of pyramidal tracts cannot be accounted for, because none of the regions of the brain intermediate were preserved. In the protocol it was mentioned that no changes were grossly visible. There is nothing in the cortex, however, to account for the decrease of nerve cells, so it may be inferred that this was secondary to the pyramidal changes. But whether the pyramidal degeneration was due to hemorrhages too slight for gross recognition, or was a primary affair, cannot be decided.

The clinical diagnosis was difficult because of the short time in the hospital, but was a question between senile dementia and arteriosclerotic insanity. From the morphological findings, arteriosclerosis may be excluded, and the absence of vessel changes and atrophy of convolutions excludes senile dementia, if these be proper criteria. The psychosis might be explained by the factor which produced the pyramidal tract degeneration (could this be determined), but with the data at hand, no diagnosis can be made.

CASE X. O. H., Path. No. 1269. Male, age fifty-three years, carpenter. Admitted to Danvers State Hospital July 29, 1908; died Aug. 31, 1908.

Said to be no insanity in the family. Born in Sweden,

came to the United States at twenty years. Married for ten years, no children, worked at trade of carpenter. No serious illnesses, used tobacco and alcohol moderately. Was considered queer for some time. Onset in February, 1908, when he complained of pain in the epigastrium; stayed in bed. One day climbed to the roof of the house and fell off, breaking some ribs. Was sent to the Boston City Hospital, where he remained four weeks. After leaving hospital acted queerly and was threatening. Thought people were talking about him and that police were looking for him; was noisy and excited. Sent to Danvers State Hospital two weeks later.

Knew date and year, but not the month or sort of place he was in. Education poor. Very weak and was put to bed. Complained of pain in epigastric region. Implored physician not to send him away as he had heard that he was to be taken away and killed. Admitted auditory hallucinations. Was quiet most of the time. Memory cloudy.

Physical examination on admission: Fairly nourished, well developed, anemic, bronchial breathing over left apex. Heart negative. Arteries hard, sways in Romberg position. Pupils negative. Reflexes normal. Albumin in urine.

Autopsy twenty-two hours post-mortem by E. T. F. Richards and M. M. Canavan: Unequal pupils, emaciation, acute peritonitis, enlarged mesenteric and retroperitoneal lymph nodes, injection of mesentery, purulent bronchitis, acute vegetative endocarditis, acute ulcerative colitis (healing), acute diffuse nephritis, chronic fibrous obliterative pleuritis, necrosis perinephric fat (?), chronic fibrous pericarditis, subacute perisplenitis, atrophy of stomach, fat replacement of pancreas, hypertrophy of prostate (slight), inequality of thyroid lobes, chronic leptomeningitis (sulcal), calvarium thin.

Brain weight, 1,530 gm.

Cause of death: Dysentery.

1269. The pyramidal cells show marked changes, but since they are not decreased in number, these may be regarded as terminal. All are prominently pigmented. There is a subpial gliosis and all glial cells contain pigment. The intima of the blood vessels is moderately thickened in places. The adventitial nuclei are increased in number and the amount of adventitial pigment is increased. The spinal cord is negative. These changes indicate a senile condition of a low grade.

In the gross autopsy findings, there is nothing outside the terminal condition which can be regarded as conclusive.

Clinically the case was diagnosed as involutional melancholia, and this agrees with the cortex findings, which indicate senile disturbances of some sort.

At autopsy, emaciation and atrophy of stomach were noted, and for some time before the onset of mental symptoms the patient complained of pains in the epigastrium. It may have been that there was some stomach disturbance that produced the cachexia and that this was a factor in producing the mental disturbance.

DISCUSSION.

Summarizing these data, it is found that none of these cases fall in the organic group. One (850) is a senile dementia case with rather slight changes in the brain and distinct visceral lesions; one diagnosed as senile paranoia (896) is accepted as such, since certain slight senile changes were found in the brain and other findings in the body which might indicate a disturbance of nutrition. Two diagnosed as involutional melancholia (969, 1269) were accepted as such because slight senile changes occurred in the brain, and some toxic disturbances were indicated in each. One diagnosed as collapse delirium (976) was accepted as such from the clinical history, although nothing was found in the morphology to confirm the diagnosis. One case left unclassified clinically (1090) was called toxic from the slight brain findings and the marked lesions found in the trunk viscera. One in which the clinical diagnosis was left open between senile dementia and arteriosclerotic insanity (1204) was placed on the unclassified list since both these conditions could safely be excluded, but no definite diagnosis was made because lesions were found in the nervous system which could not be explained from the material at hand. Two cases (1013, 1095) in which dementia precox was diagnosed were accepted as such because certain abnormal conditions in the brain, probably of congenital origin, were found in each case which were taken as possibly indicating hereditary defects. In one case in which dementia precox was clinically preferred (904), this condition was ruled out through absence of abnormal findings in the brain, and manic-depressive insanity given the preference by a process of exclusion.

In these ten cases the diagnoses made from the morphological findings were changed in two cases (976, 1013) after comparison with the clinical histories. One was due to the fact that the psychosis, a delirium, resulted from a functional stomach disorder that could not be recognized post mortem; the other was a case in which the brain of a dementia precox had undergone certain senile changes. Of the clinical diagnoses, on comparing with the morphological, one was corrected (1204), and two left unclassified were in a measure cleared up (1090, 904). Counting the unclassified as errors, there were three errors in the clinical diagnoses of these ten cases (1204, 1090, 904). Of these, one was due to the poor histories and inability to communicate with the patient; one was probably due to the fact that the patient died the same day that he was admitted; and one error was made because enough importance was not assigned to the disturbance of bodily functions as a causative factor in mental disease. Errors are liable to occur, then, in both the morphological and clinical diagnoses of a case, but when the two are compared it is believed that fairly accurate conclusions may be reached.

V.

A Study of the Senile Spinal Cord In Cases of Mental Disease.

BY ARTHUR S. HAMILTON, M.D., MINNEAPOLIS, MINN.,

Instructor in Neuropathology and in Clinical Neurology in the College of Medicine, University of Minnesota.[*]

(From the Laboratory of the Danvers State Hospital, Hathorne, Mass.)

A certain degree of muscular enfeeblement in the aged has been recognized for many years, but in spite of abundance of clinical material it is only recently that the clinical and pathological features of this condition have been at all clearly pointed out, and even at this time the varying terms employed by different investigators leaves something of uncertainty as to the exact condition meant to be described.

In the *Centralblatt für Nervenkrankheiten* of 1890 Dr. W. R. Gowers called attention to a condition of weakness of the legs coming on in old people, and to it gave the name "senile paraplegia." In Gowers' words, "Its characteristic is simple weakness of the legs with some slowness of movement, but without wasting, sensory disturbances or reflex alteration. The knee jerk is normal and there is no foot clonus. The malady develops very gradually and is slowly progressive, although it seems seldom to attain such a degree as to prevent standing." Gowers states that this is the earliest description of the condition in literature and Allbutt, in his "System of Medicine," [1] calls attention to the same subject in a brief paragraph, reporting two cases, and gives Gowers the credit of the first description.

In 1875, however, von Leyden [2] in his "Klinik der Rückenmarkskrankheiten," had described a paralytic weakness coming on in old people as follows: "The decrease of muscular power and energy is a natural and regular result of progressing age. Sometimes, however, there develops such a high grade of weakness, and it comes so early and so quickly, that it must be regarded as paralytic. The weakness is shown most markedly in the gait, which is stiff, slow and dragging. The legs are scarcely raised, are dragged along the ground and the steps are small. On account of the increased uncertainty and lack of steadiness the patients are compelled to walk with a stick or crutch. It consists of an unequivocal high-grade paralytic weakness, which, however, only exceptionally reaches such a degree that the patient is unable to walk. Sensibility in the majority of cases is intact. The bladder is seldom involved (incontinence or retention); often there is constipation. The leg muscles are flabby; in many cases of good girth, but sometimes markedly atrophied. The upper extremities, though not taking part in the condition in so striking a manner, are, nevertheless, weak and atrophied, but they are not really paralyzed and their functions are not disturbed to the same surprising degree. The mental functions are sometimes quite unimpaired, though there may be disturbance in this sphere independent of the paralytic condition. In many cases there are simultaneous, wandering, tearing pains in the extremities, joints and muscles. The malady progresses gradually, seldom in acute exacerbations. It is seldom retrogressive, and only in rare cases remains stationary, though occasionally it may come to a standstill, or an improvement may even manifest itself."

Also, in 1862, Empis [3] gave a clear clinical description, evidently referring to the same condition, under the title "Progressive Muscular Enfeeblement of the Aged," but he failed to find any anatomical basis for the symptoms, thought they did not, properly speaking, constitute an organic malady, but were more closely allied to a group of neuroses, and pointed out particularly their resemblance to chlorosis and made use of the term "*chlorosis senilis.*" He stated that the entire muscular system was equally involved and that the condition was by no means hopeless.

Other authors of even earlier date have referred more or less clearly to the same subject, and excellent historical reviews can be found in Lhermitte's thesis on the "Paraplegias of the Aged," where the matter is carried back to Portal's article in 1804, and in Siemerling's article in Schmidt's "Lehrbuch der Greisenkrankheiten."

On the pathologic side, also, considerable work has been done, and though von Leyden's [2] article is probably the first which at all clearly sets forth the anatomical basis of the condition, there are frequent references in the literature for many years past to different pathologic conditions found in the spinal cord in old age. Thus Rokitansky [4] and Geist [5] describe atrophy of the cord and thickening and serous effusion in the meninges. Virchow [6] recognized that in old age the neuroglia tends to predominate over the nervous elements and becomes usually permeated by a greater or less number of amyloid bodies. Charcot [7] recognized atrophy and degeneration of cells and pigmentation and fatty changes as evidences of old age.

In the article already mentioned, von Leyden [2] described the relative absence of gross atrophy in the cord as compared with the brain; the presence of marked increase of corpora amylacea, especially around the central canal, about the vessels and in the periphery of the cord and in lesser numbers in the gray matter; atrophy and pigmentation of the ganglion cells; frequent severe changes in the vessels, especially of the small arteries, and the occasional finding of granule cells. He also described the very infrequent presence of degeneration of the white matter, especially in the posterior part of the lateral columns and in the columns of Goll.

Gowers [8] thought the cerebral cortex was the seat of the central disturbance. Allbutt [1] located it in the cord. Neither offered any anatomic evidence.

Durand-Fardel [9] insisted that the cord in this condition is more atrophied than the brain, but this does not reflect the views held either then or now.

Campbell [10] described in the spinal cords of the

[*] Working as special laboratory interne, Danvers State Hospital, and in connection with the Harvard Summer School of Medicine, 1900.

aged insane a destruction of nerve fibers, especially in the lateral and posterior columns; thickening of the walls of the blood vessels; dilatation of the perivascular spaces; abundance of corpora amylacea; hypertrophy of the ependyma of the central canal and pigmentation of the ganglion cells.

In 1899 Nonne [11] studied the cords of ten individuals from seventy-eight to eighty-six years of age and found increased neuroglia, atrophy of the nerve fibers of the posterior and lateral columns and thickening of the vessel walls without inflammatory change. In his opinion there was no correspondence between the grade of arteriosclerosis and the degree of change in the cord.

In 1900 Sander [12] described three forms of degeneration in the senile spinal cord: (1) A mild form with slight diffuse degeneration of the myelin sheath, slight secondary gliosis and a slight degeneration of the cells of the cord. This condition he considered merely a physiologic senile change. (2) A gross form with diffuse myelin-sheath degeneration, formation of foci of a high degree of sclerosis and a marked cellular degeneration. (3) A form, often pre-senile, with acute degeneration and multiple foci of arteriosclerotic degeneration of the spinal cord. All these are dependent on senile vascular changes, which in No. 2 are more or less universal and in No. 3 seem to be more localized. This senile degeneration affects, first, merely the margin of the cord, but the cerebellar and crossed pyramidal tracts are later also involved. The posterior columns are less affected than the lateral, but in some cases there is a loss of patellar reflexes. Bladder and rectal disturbances, when present, are due to a grave degeneration in the gray substance, especially in the ganglionic cells.

Naka,[13] in a study of 17 cases, all senile dementia, arrived at much the same conclusions as Sander. He found slight loss of light reflex in the pupils, tremor of the tongue and hands and arteriosclerosis in the temporal and radial arteries. The knee-jerks were present in all, in some active, and in one third of the cases a spastic condition could be demonstrated.

The gross strength in the lower extremities was greatly weakened. Sensibility could be tested only with difficulty, but no coarse defects were found. The gait was often affected and was then uncertain, slow and swaying, with short steps. The Romberg sign, as well as bladder and rectal trouble, was present at times.

Oppenheim [14] refers to a senile paraparesis in which there may be contractures and even sphincter and sensory disturbances.

Ferrio and Bossio [15] studied the superficial and deep reflexes in 150 males and 100 females, varying in age from sixty-five to ninety-three. None of them showed any specific diseases of the nervous system. The patellar reflex was increased in 32.2% and absent in 20.4%. Foot clonus was present in 19.2%. The abdominal reflex was absent in 56.8%; the plantas reflex was absent in 31.6% and the cremasteric in 58%. Spastic conditions were found more often in men than in women, and the abdominal reflex was absent in women more often than in men. Six cords were examined with the following findings: The white substance was deficient in white fibers, the neuroglia was increased and the ganglion cells were deficient in number and showed some degeneration.

In 1907 Lhermitte, in his thesis, "Paraplégies des Vieillards," contributed an elaborate study of the subject. He divides the cases into three groups: (*a*) Lacunar (cerebral), (*b*) myelopathic and (*c*) myopathic. Of the myelopathic he recognizes three types: (1) Perivascular sclerosis (type Demange), (2) marginal sclerosis, (3) combined senile sclerosis involving especially the lateral and posterior columns.

In this country there have been only a limited number of contributions. In 1896, Hunt,[16] in an article on the pathology of paralysis agitans, referred briefly to the similarity in the pathology of this condition to that of senility. Seven years later Hirsch [17] contributed an elaborate article on the clinical phase of the subject. He ascribed the condition wholly to an arteriosclerosis of the spinal cord, but offered no anatomic proof, except in one case, and even in this referred only to the condition of the blood vessels and the ganglion cells. The next year Collins and Zabriskie [18] set forth the same view, based on clinical evidence and one post-mortem study. Collins [19] has since written on the same subject.

During the summer of 1909, at the Danvers State Hospital for the Insane, at the suggestion of Dr. E. E. Southard, and with his aid and direction, I made a study of the accessible material bearing on the problem of the spinal cord changes in the aged insane. I wish to record my obligations to Dr. Myrtelle M. Canavan, as well as to Dr. Anna H. Peabody, of the Danvers staff, for their aid and courtesy.

At the outset I found the cords of 72 individuals, all of whom had died when seventy or more years of age, the oldest being ninety-four. In order to guard against the inclusion of pathological changes due to something other than old age, I rejected all cases in which the following conditions were present: Gross cerebral disease, such as hemorrhage or thrombosis, cases of brain tumor and epilepsy, and, finally, all cases where, at the autopsy, anything indicating gross and localized disturbance of the nervous system was found. With these restrictions applied there were 54 cases remaining in whom the changes might fairly be ascribed to old age and the conditions necessarily incident thereto. It is on the findings in these 54 cases that my paper is based.

In nearly all instances the mental condition of the patients had been that of senile or organic dementia. Examination as to the clinical condition of such cases is always difficult and more or less unsatisfactory. In a large majority of instances the patients were very resistive and, in addition, the mental weakness was usually so great as to interfere with the patient's answers, so that the records are often short and sometimes cannot be wholly relied upon.

In the following tables certain clinical features are given in tabular form.

TABLE I.

FORM OF MENTAL DISORDER.

	Cases.
Senile dementia,	36
Organic and arteriosclerotic dementia,	12
Terminal dementia (original diagnosis uncertain),	4
Delusional insanity,	1
Alcoholic insanity,	1

TABLE II.

DURATION OF MENTAL DISEASE.

	Cases.
33 years,	1

Tubercular enteritis,	1
Senile inanition,	2
Senile inanition and aortic thrombosis,	1

In practically all cases the usual manifestations of old age were present. The arms and legs were flabby, with dry, loose skin, but there were no instances where strictly localized atrophies were referable to any disorder of the nervous system. Muscular strength and control were much impaired, and, in some instances, this condition had reached a high degree. Usually the loss of strength came on very gradually. In the early stages the movements were awkward and unsteady. In walking the feet were spread wide apart and the individual often fell. The spastic, staggering gait became more and more feeble and tottering, with steps that were shuffling, until at last there was complete loss of power and the individual was constantly confined to bed.

Sensory ailments were much more difficult to demonstrate than motor disturbances. Several times there was clearly a diminution of sensibility for touch, pain, heat and cold in the feet and legs. Once a similar condition was mentioned in the hands and arms. In an even larger number of instances no disturbances whatever could be elicited in a fairly satisfactory examination, but in much the larger number of cases the result was very unsatisfactory on account of the mental condition.

The reflexes varied considerably and, as already mentioned, it was often difficult or impossible to obtain an accurate response. In 44 instances the knee jerks were normal 11 times, increased 24 times, diminished 7 times and not obtained twice. In 30 instances the Achilles jerk was normal 8 times, increased 10 times, diminished twice and not obtained 10 times. Ankle clonus was present twice and both times in one leg only. In 26 instances the deep arm reflexes were normal 6 times, increased 12 times, diminished 5 times and not obtained 3 times. In 26 instances the plantar reflexes were normal 13 times, increased 8 times, diminished 3 times and not obtained twice. The Babinsky phenomenon was found once. In 17 instances the abdominal reflex was normal 4 times, increased 3 times, diminished 4 times and not obtained 6 times. In 32 instances the pupillary reactions were normal 12 times, increased once, diminished 18 times and not obtained once. In 18 instances the pupils were equal 16 times and unequal twice.

Incontinence of urine and feces from organic trouble could not be differentiated from the same condition due to mental failure. In 31 instances, when reference to the condition was made, 15 individuals were tidy and 16 were untidy.

Tremor was frequently present. It was observed most often in the hands and tongue, but it was found also in other parts of the body and was occasionally worse on one side of the body than on the other, or was even strictly unilateral. Twice it was noted as absent, and, when its location was given, it was general once, once in the lips and tongue, twice in the hands, 4 times merely described as localized, 11 times in the tongue and hands and 5 times it was mentioned as coarse without reference to its location.

Albumen and casts were frequently found, the former almost always as a trace and the latter as hyaline.

At the post-mortem examination, gross changes in the cord were rather noteworthy for their absence. A moderate degree of atrophy was frequently present, but, so far as the records show, this never reached such a degree as is commonly found in the brains of old people. It would have been very difficult to determine the weights of

the cords, but the following brain weights are given as having an indirect bearing on the matter.

Brain weights.	Cases.
1,450–1,500 gm.,	1
1,400–1,450 "	2
1,350–1,400 "	5
1,300–1,350 "	4
1,250–1,300 "	8
1,200–1,250 "	4
1,150–1,200 "	3

1,000–1,050 "	4
950–1,000 "	5
900–950 "	0
850–900 "	2
Weight not given,	7

The pia-arachnoid and dura were found thickened, but rarely was the change great. In two instances cartilaginous-like plates were found in the pia-arachnoid. Rarely a relative condition of softening was observed in different parts of the cord. Ordinarily the cord substance was tough on section and paler than normal. Gross vascular changes would naturally be less easily demonstrated than in the brain, but so far as observed they were decidedly infrequent. Thus hemorrhage was found only twice in the 54 autopsies, and then only in very minute form. Arteriosclerosis elsewhere, however, was pronounced, as is seen in the following tables.

Arteriosclerosis in the brain.

Not mentioned or questionable,	2

Three or more areas from each cord were studied and portions from each area were preserved in alcohol, formalin and Zenker's fluid. The Marchi, Nissl, Weigert myelin, Mallory's neuroglia, eosin and polychrome methylene-blue, Weigert elastic and Benda stains were employed.

Microscopic lesions in the cord were as common as gross lesions were rare. In not a single instance was it possible to say that the fiber tracts were normal, to say nothing of vascular changes, of the presence of abnormal quantities of pigment inside and outside the cells, of cell atrophy and of increase of neuroglia and corpora amylacea.

Marchi preparations invariably showed breaking down of the tissues. In the meninges occasional large black masses were seen, and small black droplets were almost constant. The former may have been artefacts, especially as intermediate forms between the large and small masses were not common. A golden-brown pigment entirely distinct in appearance from the black masses was also found. This occurred mostly as small granules of the same size and much the same distribution as the small black masses. Both were seen at times intracellular, but much more often free. In addition to the small brownish granules, there appeared in the meninges large spindle-shaped masses (Fig. I) of the same color, having very much the outline of adult connective tissue nuclei. In some cords they were very abundant; in others scarcely to be found. It was also noticeable that they appeared more often in the cervical cord than in the other parts, and much more often in the lateral regions of this part of the cord than in the dorsal and ventral aspects. There did not appear to be any relationship between the number of these spindles and the amount of pigment of other sorts. Both the black and the golden-brown pigments were seen in the walls of the vessels of the meninges and the cord, especially in the intima (Fig. II) and media, in varying amount. Large phagocytic cells were frequently found within the lumen containing both kinds of pigment. Small golden-brown spindles, similar to those of the pia-arachnoid, except smaller, were found in the media.

Within the cord substance the black pigment was also seen, both in the white and the gray matter, and about equally abundant in the two. Very commonly it was scattered diffusely through the cord, sometimes in very large amounts, much more often in small quantity, and in no instances was it entirely lacking. Frequently there was a line of this pigment along or around the vessels, within the neuroglia or connective tissue and not really connected with the myelin sheaths. This appearance was much more pronounced in the white than in the gray matter. As a rule, the black pigment was much more abundant in the posterior and lateral columns than other parts of the cord, but it was largely absent where Weigert preparations showed a well-marked, long-standing sclerosis. Thus, if in a portion of the posterior columns there was more or less complete absence of nerve fibers and the presence of an increased amount of neuroglia, there would be found in this area not many black granules, but in the portion of the posterior columns adjacent their number would be decidedly increased.

In addition to this more or less diffuse appearance of the granules in the large majority of cases, there were a few in which they were gathered in localized groups and appeared as much larger granules. They then appeared invariably in the direct and crossed pyramidal tracts, the direct cerebellar tracts and the posterior columns, giving very much the same appearance as is seen in the spinal cord degeneration so often found in pernicious anemia. In these cases, in the area specially involved, the balloon appearance of the myelin sheaths was also often found.

The Marchi preparations also showed an acute degeneration of the anterior and posterior root fibers (Fig. III), more marked in the latter than in the former, but very unequal in different cases, and even at different levels of the same cord.

Fig. XXII.

In every instance the ganglion cells contained large amounts of pigment (Fig IV), appearing, when prepared by the Marchi method, more like the golden-brown variety than the black masses. A similar appearance was found in the neuroglia cells, though to a much less degree, except in the neighborhood of the central canal, where the proliferated cells were about as deeply pigmented as the large ganglion cells.

In the sections stained by the Weigert method, and calculated to show more slowly progressive changes, the alteration was equally striking. The areas most involved were the direct and crossed pyramidal tracts, the direct cerebellar tracts and the posterior columns, and in not a single instance was it possible to say that all of these columns were normal. The peripheral sclerosis so much emphasized by Sander, Lhermitte and others was found, but apparently not in so high a degree as those authors insist upon. In a large proportion of the cases there was an outer circle of the cord, paler than the remaining portions, but very frequently sections from the same cord prepared by other methods failed to substantiate the presence of any marked sclerosis there, and the paler ring was doubtless in many instances merely an artefact. Naka [13] also notes the failure of the neuroglia-stains to confirm this peripheral sclerosis, but still insists on the presence of such a sclerosis and explains the lack of a neuroglia reaction by the recent development of the sclerosis. Aside from the more or less marked thickening of the peripheral ring of neuroglia, which was very common, three cords showed a well-marked marginal sclerosis, such as is seen in Fig. V. In these three instances the evidence of sclerosis was as marked in the neuroglia and Nissl preparations as in the Weigert preparation. In addition, more or less clearly defined wedge-shaped marginal sclerosis (Fig. VI) was fairly frequent. Whether this latter appearance conformed to the wedge-shaped areas so much emphasized by Sander, I cannot say. Certainly I could not connect them with definite vascular changes, as Sander was able to do. Aside from this marginal appearance, the most frequent sclerosis was in the posterior columns. In the lumbar region this area was diffusely sclerosed. (Fig. VI.) Higher up the change was better defined and more limited to the columns of Goll, but at all levels the dorsal part of the posterior columns was more likely to be involved than the ventral, and in many instances, especially where the change was slight, only a limited area of the posterior columns was affected, and this often of very irregular formation and of very variable position. (Figs. VII, VIII, IX, X.) Lhermitte [20] found the degeneration greater in the lumbar and lower thoracic regions than higher up in the cord. Sander [12] believes that the lateral columns are involved much earlier than the posterior. I found no evidence of this.

The next most frequent area involved was the lateral columns, and here the intensity of the process rarely exceeded or even equaled that in the posterior columns. The change also was more diffuse, but equally variable in its distribution, and the more or less localized sclerosis frequently seen in the posterior columns was almost never observed. In the following diagrams are indicated the outlines of the rather irregular areas involved in many cases. (Figs. XI–XVIII.)

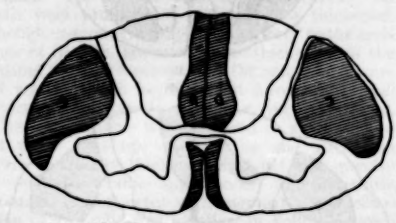

Fig. XI.

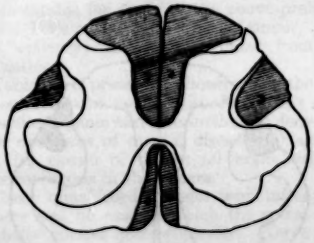

Fig. XIII.

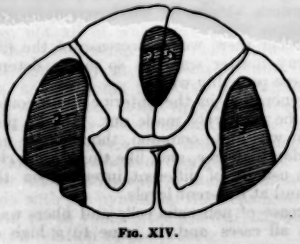

Fig. XIV.

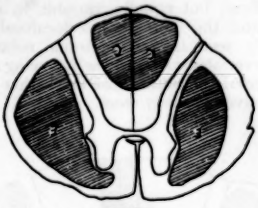

Fig. XV.

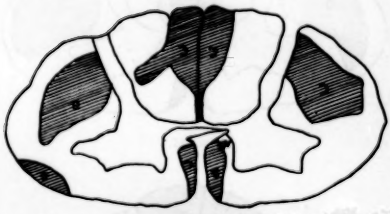

Fig. XVI.

Fig. XVII.

Fig. XVIII.

Whether there was a decrease of the fibers in the gray matter was not so easily determined, but there probably was.

Degeneration in the anterior roots could very rarely be positively made out. In the posterior roots it was quite common, though only in slight or moderate degree, and, like the Marchi changes, it was usually of different intensity on the two sides and at different levels.

Increase of neuroglia cells and fibers was present in all cases and in some to a high degree. Thus the glial ring at the periphery of the cord (Fig. XIX), already mentioned, was often greatly increased, and the glial framework of the cord was also often very prominent. Always, where a positive degeneration could be demonstrated by the Weigert method, there was found a marked increase of neuroglia. Occasionally large neuroglia cells with smaller processes were found throughout the cord. Perivascular increase of neuroglia (Fig. XX) was common.

As further evidence of senile neuroglia change, the central canal was commonly closed, and even more constant was the increase of ependymal cells about this region. Not infrequently, however, the central canal was surrounded by a distinct layer of columnar cells, and the canal appeared as if distended. Three times conditions justifying the term "hydromyelia" were found. (Fig. XXI.)

Corpora amylacea were observed in sections stained by all the methods employed, but they were brought out especially well by the stain for elastic tissue, and by Benda's stain. The variation in the numbers seen in the different cases, however, was so great that it seemed explicable only on the basis that in some cases the fixation, or staining, or both, were such as not to bring them out. In the examination of some cords, scarcely a single one could be seen. In other cords they were present in great numbers, even when all other pathological aspects of the two cords seemed about the same.

As a rule, the corpora amylacea were found in greatest abundance on the external aspect of the dorsal horn just after the root enters the cord and in the neighborhood of the substantia gelatinosa. They were seen next most frequently in the posterior columns, especially in their dorsal portions. They occurred with about equal frequency in the periphery of the cord, especially laterally, and around and in the neighborhood of the central canal. Much less commonly and in much smaller numbers they were found in other parts of the white matter. A considerable number were found in the gray matter, but not nearly so many, excepting in the substantia gelatinosa, as appeared in the white matter. There was also noticeable a special tendency for the corpora amylacea to appear in the peripheral glial ring (Fig. XXII) and in the bands which constitute the glial framework of the cord. In the latter relationship, therefore, they appear to follow along the vessels of the interior of the cord, as has been pointed out by von Leyden [2] and others, but it seems to me their essential relationship is with the glial band, and their connection with the vessel is merely accidental and dependent on the fact that these thick glial bands are found most often along the vessels. The tendency of the corpora amylacea to appear in the peripheral and perivascular glial bands, in both of which places they are entirely apart from the myelin sheaths, tends to support the view of Redlich [21], Obersteiner [22] and Nambu [23], that the corpora amylacea are derived from the neuroglia and not from the myelin sheaths or other elements

of the cord. I did not, however, find the transition stages between neuroglia cells and corpora amylacea, as pointed out by Nambu, though no special effort was made in this direction.

Von Leyden found the corpora amylacea most frequently about the central canal, in the substantia gelatinosa and along the vessels. Siemerling [24] thought they were most abundant about the central canal, and Nambu [23] found them most frequently about the periphery, at the anterior border of the posterior roots, in the posterior columns and in the neighborhood of the central canal.

It is apparent, therefore, that while the corpora amylacea occurred most commonly in those parts where degeneration of the nerve elements was greatest, it was by no means always true that in individual cases this connection could be made out.

In the ganglion cells of the cord, both large and small, stained by the Nissl method, there was a high degree of pigmentation and a marked tendency to the breaking up of the stainable material (Nissl bodies) and an atrophy of the cells, which, in some cases, led to their complete disappearance. It was remarkable, however, to see how large a portion of the cell could be taken up by the pigment and yet the remaining part contain a fairly normal-appearing nucleus and Nissl bodies.

In all the sections studied, scarcely a single ganglion cell which did not contain at least a considerable amount of this clear yellow pigment was seen. Ordinarily a portion of the cell was given over to pigment, the adjacent part contained stained fine granules, as if the Nissl bodies had been broken up, and another portion would contain nucleus and fairly normal-appearing Nissl granules. Some cells were occupied solely by pigment and stained fine granules, and in a few instances the cell body was made up of a diffusely stained material without evidence of granular formation. Not infrequently clumps of pigment were found, which apparently represented cells entirely replaced by pigment. Similar cell changes have been described by many authors and have been named by Nissl "sclerosis of the ganglion cell."

Rarely, but much more frequently in some cases than others, the degenerating ganglion cells were surrounded by neuroglia cells, somewhat similar in appearance to the satellite cells of the cortex. These, however, are by no means so commonly present or in such numbers as in the brain, and when found at all they are not necessarily around the most diseased cells. Moreover, the most diseased cells very frequently have no such neuroglia cells about them. Very rarely a small group of neuroglia cells is seen possibly representing the site of a former ganglion cell.

Cells showing the central neuritis change were occasionally encountered and, in a few cases, quite frequently.

Peripheral position of the nucleus was common. Vacuolization of cell bodies and the nucleus was infrequently observed. The cells of Clarke's column seemed more affected than the other groups of large ganglion cells.

Nearly all the vessels showed a thickening of the wall, and some showed a distinct lessening of the lumen. The vessels also appeared increased in numbers in the posterior and lateral regions of the cord, much less so in the anterior region. The intima was chiefly involved. Its cells were proliferated and the coat thickened, though unsymmetrically so. Contrary to the findings of Sander, however, great thickening of the intima was not common, and the complete closure of vessels, which he found not infrequently, was observed only rarely and in a very few cases. The elastic tissue was increased in amount, and at times split up. The media and adventitia were commonly thickened, and not infrequently presented a hyaline appearance. The adventitia contained phagocytes with pigment. Vacuolization of the cells and a yellow or yellowish-green pigment in the perivascular spaces was often seen. Perivascular nuclear increase was frequently noted, but this was usually due to neuroglia increase.

SUMMARY.

1. A review of the literature concerning the senile spinal cord demonstrates both clinical and anatomical uncertainty. It is uncertain how many separate clinical entities depend on senile spinal changes, whether physiological involution is responsible for the development of any spinal symptoms, and how far arteriosclerosis accounts for the anatomical changes found.

2. The protocols of 72 subjects dying at seventy or more years of age at the Danvers State Hospital, Massachusetts, have been examined. Eighteen cases showed a variety of conditions rendering them unsuitable for study of the above problems (cerebral hemorrhage, thrombosis, tumor, gross lesions, epilepsy) and were excluded from this investigation.

3. Tables are presented showing (*a*) the predominant forms of mental disorder in this series to be senile, organic and arteriosclerotic dementia; (*b*) the durations of mental disease; (*c*) ages at death; (*d*) causes of death; (*e*) brain weights; (*f*) arteriosclerosis in the viscera.

4. Gross spinal cord changes were infrequent, but there was no case in which the spinal cord was wholly normal microscopically. Nerve fiber alterations were constant. Vascular changes, pigmentation, nerve cell changes, neuroglia alterations and corpora amylacea were also studied.

5. Marchi preparations invariably showed alterations, not all of which are easily explained. When the blackenings were not diffuse they occurred preferably in the posterior and lateral columns, and in some instances a condition resembling the spinal cord appearances of pernicious anemia was closely approximated. In this latter group of cases, the lateral columns at appropriate levels showed changes in the direct cerebellar tracts adjacent to and apparently of like origin with the pyramidal tract changes. The peripheral nerve roots often showed blackenings of doubtful relation to the process.

6. Nerve cell and, to a lesser degree, neuroglia cell pigmentation was constant.

7. Weigert myelin sheath preparations invariably showed alterations in some region, preferring those mentioned in paragraph 5, again resembling the changes which accompany pernicious anemia. The posterior and postero-lateral columns formed the region of election for these chronic changes (excluding certain questionable conditions in the periphery), and posterior nerve root degeneration (of slight or moderate degree) was common.

8. Fibrillary gliosis was constant, but varying in degree from case to case, corresponding very closely with changes as demonstrated by the Weigert myelin sheath method. Mallory's phosphotungstic hematein method was used for this demonstration. Closure of the central canal and some instances of hydromyelia were found.

9. Corpora amylacea were most abundant external to the dorsal horns and in the neighborhood of the substantia gelatinosa. They were also common in the posterior columns and the periphery of the cord. The distribution of the corpora amylacea appeared consistent with the hypothesis of their derivation from the neuroglia.

10. The co-existence of marked pigmentation with relatively intact Nissl bodies in many ganglion cells was noteworthy. Many chronic changes were found. Satellitosis was occasionally displayed, as also axonal changes.

11. Vascular changes were frequent, but perhaps less marked than might have been expected.

12. Those in advanced years very frequently present a series of symptoms consisting in more or less marked impairment of muscular strength and control; a spastic, shuffling, tottering gait; a varying disturbance of the deep and superficial reflexes; tremor and sensory disturbance. These symptoms represent not merely conditions of general decay, because they may be present even when not associated with signs of decay in other parts of the body, and, on the other hand, may be absent even when such signs are present, but are constantly associated with a definite pathological change in the spinal cord, in many respects like that of pernicious anemia, and should not be interpreted as direct manifestations of arteriosclerosis.

VI.

AN HISTOLOGICAL STUDY OF THE THYROID GLAND IN MENTAL DISEASE, WITH ESPECIAL RELATION TO CHRONIC THYROIDITIS.

BY ANNA H. PEABODY, M.D.,
Assistant Physician at the Danvers State Hospital, Hathorne, Mass.

THE present study of the thyroid gland in cases of mental disease is mainly histological, but contains certain anatomical and clinical correlations. Such a study is appropriate both on account of the general trend of recent speculations concerning ductless glands and by reason of certain special claims concerning the value of partial thyroidectomy in dementia precox. It was Berkley's paper [1] on partial thyroidectomy, read at the Cincinnati meeting of the American Medico-Psychological Association, 1908, which directly occasioned this study, as it was hoped to show by a study of thyroids in dementia precox, controlled by the glands in other conditions, whether any differential conditions were obtained in dementia precox. Dock's chapter on "Diseases of the Thyroid Gland" in Osler's "Modern Medicine" [2] contains numerous references to nervous and mental states in exophthalmic goiter, and the subsequent chapter [3] describes such states in cretinism and myxedema. Similar statements appear in Ochsner and Thompson's recent book.[4]

Berkley's work, while very speculative, has the merit of not concealing the speculative character of any of his reasonings. Out of a large list of drugs employed to improve the condition of katatonics, only iodine had an effect upon the patients. Even a small dose (1-250 gr. iodine, as iodized starch) might wake the patients from their stupor, increase dermographia, heighten reflexes, increase hyperidrosis and quicken the pulse — all temporarily. Iodothyrin and desiccated thyroid also made the patients worse. Alternating treatment — thyroid, 1 or 2 gr. daily for a week, followed by alcoholic solution of lecithin daily for another week — secured some good results. Large quantities of milk were also given to these patients.

Partial ablation of the thyroid was then performed by Follis in a number of cases, with more or less rapid recovery in Cases I, II, III, IV, VIII; no results in V, VI, VII. The three unfavorable cases had been of longer duration, and Berkley

suggests that organic brain changes had set in in these cases.

Berkley's idea of the mechanism of the thyroid lobectomy procedure in procuring good results in katatonia is expressed by him as follows: "It is possible, from the symptoms, that in katatonia we have a perversion of the secretion of that organ and that partial thyroidectomy induces a return to the normal in the secretion of the remaining portion of the gland. The return to the natural state of the reflexes, the decrease of the mechanical muscular irritability, as well as of the dermographia, the loss of pigmentation, also of the doughy, pasty character of the skin (most noticeable in the prodromal and stage of mutism), and the later return to the normal both of the mental as well as physical state, are at least suggestive that partial ablation of the gland is a factor, and has something to do with the rapid recovery."

McCallum's histological results in some of the Berkley-Follis cases were as follows:

I. Female, nineteen, duration of katatonia two years nine months, partial thyroidectomy. "The alveoli are distended with homogeneous colloid, which, however, show some variations in its staining qualities. Some alveoli are filled with pale gray, others with pale pink, and others with bluish-pink color. For the most part they are larger than normal and their epithelial cells are very low and flat. In some places, however, the large alveoli are surrounded by very small ones. There is in most instances no distinct folding of the alveolar walls. In one or two alveoli, however, there is a remarkable scalloping of the epithelium by its being uplifted by capillaries."

II. Male, twenty-one, duration of katatonia about six months, partial thyroidectomy. "The thyroid is rather fibrous-looking; strands of connective tissue subdivide it into lobules. The alveoli are, for the most part, large, but very irregular in form, with buds and infoldings. The epithelium is cubical, distinctly higher than normal, but not as high as that seen in exophthalmic goiter. There are numerous small alveoli associated with these larger ones, and these also have high epithelium. There are some scattered patches of lymphoid tissue through the thyroid."

III. Female, twenty-eight, duration of katatonia about four months, partial thyroidectomy. "A part of the gland seems a little firmer than the rest and is more translucent. The gland in general is almost normal looking; it is reddish-gray and quite homogeneous. On section, rather translucent, with scattered points of yellowish opacity which are visible only on most careful inspection." "It is composed of uniform, rather small, alveoli, unusually rounded in form and showing no infolding of the epithelium. The alveoli are lined with a flattened epithelium, which is perfectly uniform and normal-looking throughout. The blood vessels show some evidences of calcification and hyaline degeneration in their media."

IV. Male, nineteen, duration of katatonia about eight months, partial thyroidectomy. "Portion of right thyroid removed, weighing 2.96 gm. Small mass of soft tissue, homogeneous and uniform in appearance throughout. On cut surface the tissue is moist and glutinous, grayish-red. No apparent excess of fibrous tissue, no nodules." "It is composed of alveoli of moderate size, very round and smooth in outline, and of fairly uniform size. They contain a good deal of homogeneous colloid. The alveoli are lined with flattened epithelium, which is entirely uniform in character. The connective tissue forms some quite coarse bundles throughout the gland, which carry abundant blood vessels, but on the whole it does not seem to be markedly increased in amount. There is an unfolding of the epithelial layer." "Second ablation, Jan. 17, 1908. Microscopically the alveoli are distended with colloid, which is thin and pale, staining sometimes lilac, sometimes pink. The alveolar walls are thin and the epithelium is low and flat. The alveoli in general are larger than in the first specimen. Some of them are surrounded by small columns of other alveoli of smaller size, but there is no direct evidence of infolding of the epithelium. The connective tissue is abundant."

Farrar examined the thyroid tissue from Case VIII.

VIII. Male, twenty-five, duration of katatonia about five months, partial thyroidectomy. Thyroid: "The only divergence from the normal was the distention of practically all the follicles with colloid material. The lining epithelial cells are obviously much flattened, there being nowhere any cylindrical cells. Many follicles were of considerable size and obviously represented confluences of several follicles. In many instances the distended follicles occupied the microscopic field, the interfollicular connective tissue fibers being reduced to a minimum. In themselves, the connective tissue and the blood vessels showed no pathological changes; also there was no evidence of any inflammatory process."

For the convenience of future workers, the results of thyroid examination in five cases of dementia precox autopsied at the Danvers State Hospital are here printed:

1034, 12756, male, thirty-five, dementia precox, two years; pulmonary gangrene, recent. There is no gross change in the thyroid. Microscopically, no increase is noted in either interlobular or interfollicular connective tissue. The blood vessels are normal. The follicles are uniformly small and regular in outline, the epithelium is usually flattened or low cuboidal. The colloid in the follicle is deeply evenly staining and retracted from the epithelium. No colloid is seen in the interstitial tissue.

1036, 11,317, male, twenty-seven, dementia precox, five years; multiple thrombi of heart, recent. Grossly nothing was noted at autopsy. Microscopically, the connective tissue, both interlobular and interfollicular, shows a slight increase and blood vessels are normal. The follicles are generally small, fairly regular in outline and the epithelium usually cuboidal. Colloid in the follicle is deeply but unevenly staining, in some cases retracted from the epithelium and containing crystals and vacuoles, in others filling the follicle, but unevenly staining. A small amount of colloid is noted in the interstitial tissue. There are occasionally clumps of cells.

1062, 7987, female, thirty-eight, dementia precox, eleven years; pulmonary tuberculosis, one + year. In gross appearance the thyroid is very thin. There is no increase of connective tissue and the vessels are normal in appearance. The follicles are of varying size, and in outline some are regular and others contain infoldings of epithelium several layers in thickness. The epithelium is in some instances flat and in others cuboidal and often reduplicated. There is a marked variation in the colloid, in some cases pale, containing many vacuoles, with epithelium and red blood cells, and in others the colloid is deeply and evenly staining, and in

most instances fills the follicle. There is a small amount of colloid in the interstitial tissue. Occasional clumps of cells are noted.

1310, 13582, female, twenty-eight, dementia precox, congenital factors; pulmonary tuberculosis, six months. Grossly the thyroid is small and the lateral lobes symmetrical. There is but a slight increase in connective tissue, and the vessels are not notable. The follicles are usually small, some of medium size, usually regular in outline, with epithelium, occasionally flattened, but usually cuboidal. Few follicles are empty, but most contain colloid, which in some instances is pale, but for the most part deeply and unevenly stained. Several contain colloid with deeply staining center surrounded by a pale ring. In such instances the epithelium is flat. No colloid is seen in the interstitial tissue.

1317, 12143, female, forty-four, dementia precox, twenty-one years' duration; carcinoma of breast, one year. The thyroid is larger than normal, not weighed, but is quite closely connected with the mediastinal tissue. There is a slight increase in both interlobular and interfollicular connective tissue. Blood vessels are normal, but increased in number. The follicles are small, usually regular in outline, but in some cases indented with reduplication of epithelium or by blood vessels between epithelium and basement membrane. The epithelium is flat or low cuboidal. Few follicles are empty, but many contain unevenly deeply staining colloid retracted from the epithelium. No colloid is noted in the interstitial tissue.

The sections were prepared from Zenker fixed material and stained with eosin methylene blue, Mallory's connective tissue stain and phosphotungstic acid hematein.

For the understanding of such data, it is obviously necessary to study the thyroid in other conditions than dementia precox. Ramadier and Marchand have made such a study [5] showing that microscopic changes are more frequent in the insane from goitrous regions. They find microscopic changes very frequently, as often in the sane as in the insane. Of 48 cases autopsied in the institution at Doir-et-Cher, there were

	Cases.
Normal,	8
Slight sclerosis,	18
In places sclerotic,	5
Diffuse atrophic sclerosis,	14
Inflammatory changes,	3

Reviews of this work have considered the results wholly negative, apparently on the ground that 8 normal thyroids among 48 from insane patients exclude any possible relation between thyroid disease and insanity. Such a view proceeds on the broken hypothesis that insanity is a unitary condition.

It has been thought worth while to follow Ramadier and Marchand with a similar analysis of 50 cases, coming from a non-goitrous region.

The general results are shown in the accompanying table:

	Cases.
Normal, microscopically,	11
Slight chronic fibrous thyroiditis,	16
Marked chronic fibrous thyroiditis,	11
Chronic interstitial thyroiditis (mononuclear cell deposits),	*1

* In a case of acromegaly published by Barrett.[4]

	Cases.
Epithelial infolding pronounced,	18
Colloid excess (interstitial),	8
Colloid excess (follicular),	8
Exophthalmic goiter,	1

The cases of macroscopic enlargement numbered 8.

905, 12046, female, sixty-five, organic dementia, two + years; bronchopneumonia, recent.

1058, 12162, female, sixty-one, senile dementia, ?; lobar pneumonia, recent.

1091, 11332, male, seventy-four, paralysis agitans, six years; septicemia, recent.

1139, 13004, female, seventy-seven, manic-depressive insanity, thirty-nine years; bronchopneumonia, recent.

1148, 13530, female, twenty-five, cerebral gliosis with exophthalmic goitre, one + year; bronchopneumonia, recent.

1162, 13576, female, fourteen, status epilepticus, five years; status epilepticus.

1227, 11984, female, thirty-seven, epilepsy, congenital; bronchopneumonia, recent.

1317, 12143, female, forty-four, dementia precox, twenty-one years; carcinoma, one year.

The cases of small thyroid numbered 6:

1054, 12897, male, fifty-one, general paresis, two years; bronchopneumonia, recent.

1062, 7987, female, thirty-eight, dementia precox, eleven years; pulmonary tuberculosis, one + year.

1064, 12988, male, eighty-seven, senile dementia, five years; bronchopneumonia, recent.

1182, 12824, female, seventy-two, organic dementia, eight years; myocarditis, recent.

1273, 14365, female, fifty-one, neurasthenia, thirty + years; dysentery, recent.

1310, 13582, female, twenty-eight, dementia precox, congenital factors; pulmonary tuberculosis, six months.

The cases of cystic thyroid numbered 4, and, besides 905 and 1091 (see list of enlargement cases), were as follows:

1053, 736, male, seventy-two, organic dementia; bronchopneumonia, recent.

1056, 13011, female, forty-one, toxic delirium, three weeks; cerebrospinal menigitis, recent.

There are 16 cases of slight chronic fibrous thyroiditis as follows:

1031, 12719, male, eight-five, organic dementia, five years; hypostatic pneumonia, recent.

1035, 12765, male, forty-five, imbecile, congenital; bronchopneumonia, recent.

1037, 12835, male, twenty-three, juvenile general paresis, five years; bronchopneumonia, recent.

1058, 12162, female, sixty-one, senile dementia; lobar pneumonia, recent.

1059, 12175, female, seventy-eight, senile dementia, seven + years; carcinoma, one + year.

1060, 12987, male, sixty-nine, senile dementia, two + years; thrombosis, recent.

1064, 12988, male, eighty-seven, senile dementia, five years; bronchopneumonia, recent.

1126, 10854, male, forty-seven, general paresis, six years; pulmonary tuberculosis.

1139, 13004, female, seventy-seven, manic-depressive, thirty-nine years; bronchopneumonia, recent.

1148, 13530, female, twenty-five, cerebral gliosis with exophthalmic goiter, one year; bronchopneumonia, recent.

* Special group consists of toxic delirium, infection psychosis, central neuritis, neurasthenia and exophthalmic goiter.

1198, 6463, female, seventy-eight, paralysis agitans, sixteen years; nephritis.

1204, 13927, male, fifty-eight, infectious psychosis, one month; multiple thrombi.

1207, 13894, male, sixty-five, organic dementia, two + years; myocarditis, chronic.

1213, 13950, female, fifty-seven, senile dementia, six months; bronchopneumonia, recent.

1231, 13979, male, sixty-four, imbecile.

1317, 12143, female, forty-four, dementia precox, twenty-one years; carcinoma, one year.

The 11 cases of marked chronic fibrous thyroiditis are as follows:

901, 10798, female, fifty-three, brain tumor, three years; brain tumor, three years.

1036, 11317, male, twenty-seven, dementia precox, five years; multiple thrombi, recent.

1038, 12775, male, thirty-one, general paresis, one year; thrombosis, recent.

1056, 13011, female, forty-one, toxic delirium, three weeks; cerebrospinal meningitis, recent.

1063, 12239, female, seventy-seven, senile dementia; cerebral hemorrhage, recent.

1085, 11217, female, seventy-five, epilepsy; enterocolitis, recent.

1091, 11332, male, seventy-four, paralysis agitans, six years; septicemia, recent.*

1182, 12824, female, seventy-two, organic dementia, eight years; myocarditis, recent.

* There was marked sclerosis of the thyroid artery, while arteries of corresponding size elsewhere in the body showed little sclerosis.

1225, 13891, male, forty-one, general paresis, six months; purulent pleuritis, recent.

1273, 14365, female, fifty-one, neurasthenia, thirty + years; dysentery, recent.

1310, 13582, female, twenty-eight, dementia precox, congenital factors; pulmonary tuberculosis, six months.

The 18 cases showing epithelial infolding, with the exception of 1031, 1035, 1037, 1038, 1148, 1204, 1213, 1231 and 1310, given in above lists, are as follows:

984, 1750, male, thirty-eight, imbecile, congenital; bronchopneumonia, recent.

1033, 11385, male, forty-five, general paresis, four years; bronchopneumonia, recent.

1061, 6833, male, seventy-eight, senile dementia, twenty-three years; lobar pneumonia, recent.

1067, 9590, female, sixty-four, manic-depressive, seven years; multiple thrombosis, recent.

1109, 9073, male, eighty-three, delusional insanity (diabetic), fifteen years; bronchopneumonia, recent.

1112, 13262, female, forty, central neuritis, three years; central neuritis.

1212, 13955, female, thirty-seven, manic-depressive insanity, eight months; bronchopneumonia, recent.

1226, 13941, male, twenty-three, juvenile general paresis, three + years; Addison's disease, recent.

1229, 14013, female, forty-five, organic dementia, one year; brain tumor.

There are 8 cases of excess of colloid in follicles,

which, with the exception of the above listed 1056, 1064, 1109, 1126, 1139, are as follows:

1162, 13576, female, fourteen, status epilepticus, five years; status epilepticus.
1191, 13795, female, twenty-five, acute delirium, one month; acute delirium.
1207, 13894, male, sixty-five, organic dementia, two + years; chronic myocarditis.

Of the 8 cases showing excess of colloid in interstitial tissue, 7 have been previously listed, namely, 1031, 1056, 1059, 1061, 1064, 1139 and 1148; the remainder is as follows:

1054, 12897, male, fifty-one, general paresis, two years; bronchopneumonia, recent.

Thyroid in emaciation.	Total No.	Emaciation.
Normal,	11	7
Slight chronic fibrous thyroiditis,	16	5
Marked chronic fibrous thyroiditis,	11	0
Chronic interstitial thyroiditis (mononuclear cell deposits),	1	0
Epithelial infolding,	18	7
Colloid excess, follicular,	8	1
Colloid excess, interstitial,	8	1
Exophthalmic goiter,	1	0

or interstitial excess of colloid had become emaciated, so that the question arises whether such histological "excess" means excess or means defect in thyroid constituents in the body at large.

Though the pulse had not been intensively studied clinically in these cases, certain data are available. None of the "normal" thyroids had been associated with pulse-rates over 100 (75% under 90). Only 1 of 7 cases of marked chronic thyroiditis yielded a pulse over 90 (but that one over 120). The exophthalmic goiter case naturally gave a high pulse; the acromegaly case a low one. The hyperplastic and excess-colloid cases, as well as those of slight chronic thyroiditis, are variously distributed with respect to pulse.

Five descriptions of thyroid glands in dementia precox are added; three of these yielded both microscopic and macroscopic alterations (one enlarged, two small), which may or may not signify important alterations in the amount of thyroid products reaching the circulation. Two cases of briefer duration showed neither microscopic nor macroscopic alterations.

THE RELATION OF THYROID TO RECORDED PULSE-RATES IN CERTAIN CASES.

SUMMARY AND CONCLUSIONS.

The favorable results of thyroid lobectomy (Berkley-Follis) in 5 out of 8 cases of katatonia rendered a histological examination of the thyroid gland in this and allied diseases desirable. This need was partially fulfilled by the work of Ramadier and Marchand, who found, in a study of the thyroid in 48 cases of mental disease, histological changes of some sort in over 80%. These French cases came from a goitrous region and the glands showed a great predominance of sclerotic changes (77%).

As a control for the French work, 50 Danvers cases have been examined. Excluding a case of exophthalmic goitre and a case of acromegaly, about 77% of the Danvers series show changes, but a far lower percentage of sclerotic changes (56%) than the French series. Since the milder degrees of sclerosis are hard to interpret, the percentages of more marked sclerosis are interesting: Ramadier and Marchand, 29%, Peabody, 23%.

A possible relation between the thyroid gland and the process of emaciation is seen in the fact that 64% of the subjects with "normal" thyroids (11) had become emaciated under hospital or other conditions, whereas none of the subjects with chronic thyroiditis (12) showed emaciation. Again only 13% of the subjects showing follicular

The absence of emaciation in chronic thyroiditis, unless accidental in this series, forms a problem in which the parallel study of the pituitary body and other glands would be of aid.

VII.

INCIDENCE OF HEART DISEASE IN ACUTE PSYCHOSES, DANVERS STATE HOSPITAL, 1879-1909.

BY ALBERT A. HORNOR, 2D,
Student, Harvard Medical School; Special Laboratory Interne, Danvers State Hospital, 1909.
(From the Laboratory of the Danvers State Hospital, Hathorne, Mass.)

THIS study of the incidence of heart lesions in acute psychoses at the Danvers State Hospital is based upon the protocols of cases autopsied at the Danvers State Hospital over a period of thirty years, namely, from 1879 to 1909. The

protocols are quite unselected, and are those of such autopsied cases as possessed clinical histories permitting the diagnosis of manic-depressive insanity or dementia precox. Many cases which before the Kraepelinian nomenclature was adopted were diagnosed as acute or chronic mania, acute or chronic melancholia, recurrent insanity, circular insanity, primary dementia and so forth have been reclassified as manic-depressive or dementia precox after careful study of their clinical histories. The total number of protocols answering the above requirements was manic-depressive, 176; dementia precox, 106. This study led to the formation of three tables.

TABLE 1.

	Manic-depressive.	Dementia precox.
Totals considered,	176	106
Hearts normal,	73–36%	24–23%
Hearts and arteries normal,	50–28%	19–18%
Hearts with minor lesions,	39–22%	34–32%
Hearts probably normal functionally,	112	58
Coronary arteriosclerosis,	18	12

From Table No. 1 it will be seen that, of 176 autopsied cases of manic-depressive insanity, 112 (or 65%) and, of 106 autopsied cases of dementia precox, 58 cases (or 55%) possessed hearts probably normal functionally.

This difference is consistent with the fact that cases of manic-depressive insanity are more likely to die earlier in the course of their disease than are cases of dementia precox. The duration of a given psychosis has a bearing on the heart lesions found, since, the longer a case lasts, the more likely are complicating features to appear.

TABLE 2.

	Manic-depressive.	Dementia precox.
Chronic valvular disease:		
Aortic,	26	18
Mitral,	23	28
Tricuspid,	6	6
Pulmonary,	1	2
*Valvular disease functionally serious,	16	30
Parietal disease:		
Fatty myocarditis,	15	15
Fibrous myocarditis,	4	1
Brown atrophy,	2	4
Hypertrophy of heart,	21	19
Dilatation of heart,	11	5
Hydropericardium,	12	18
Chronic pericarditis,	13	19
Chronic passive congestion,	11	10
Acute endocarditis,	5	9
Cardiac thrombi,	5	5
Rupture of heart,	1	0

On looking at the second table, one's attention is first attracted by the fact that of the manic-depressive series, only 16 cases (or 9%) show valvular disease that was functionally serious, whereas, of the dementia precox series, 30 cases (or 21%) were found at autopsy with valve lesions which had probably seriously interfered with the work of the heart. Of the parietal diseases, fibrous myocarditis and brown atrophy are dropped from consideration here on account of the paucity of cases exhibiting these lesions. This leaves us with fatty myocarditis, hypertrophy of heart, dilatation of heart, hydropericardium and chronic pericarditis for more detailed consideration.

*Judging by descriptions, occurrence of obvious cardiac complications in other organs, etc.

By comparing the incidence of the individual lesions in manic-depressive insanity with the corresponding lesions in dementia precox, every lesion is found more frequently in dementia precox than in manic-depressive insanity, with the exception of dilatation of the heart, which is much more frequent in manic-depressive insanity than in dementia precox. The relation of dilatation of the heart to attacks of maniacal excitement and attendant heart strain must be left in doubt.

It is of interest to compare the incidence of the parietal diseases of the heart in the acute psychoses with the incidence of these same diseases in all psychoses as set forth in the protocols available at the Danvers State Hospital. This comparison led to the compilation of Table 3.

TABLE 3.

	All psychoses. Per cent.	Manic-depressive. Per cent.	Dementia precox. Per cent.
Parietal diseases:			
Dilatation of heart,	2.4	6.2	4.7
Fatty myocarditis,	8	8.5	14
Hypertrophy of heart,	16	11.3	17.9
Hydropericardium,	5	6.8	17
Chronic pericarditis,	7.44	7.4	17.9

From this table two facts are apparent. The first is that the relative frequency of dilatation of heart, fatty myocarditis, hydropericardium and chronic pericarditis in the acute psychoses is above the average in all psychoses considered collectively. The second fact is that, while the relative frequency of hypertrophy of heart in manic-depressive insanity is below the average, in dementia precox the relative frequency of hypertrophied hearts is slightly above the average.

Finally, this study of the incidence of heart lesions in acute psychoses at Danvers State Hospital, 1879–1909, may be summarized by the following statements:

1. The percentage of hearts probably normal functionally is higher in manic-depressive insanity than in dementia precox.

2. Dilatation of heart occurs more frequently in manic-depressive insanity than in dementia precox.

3. Leaving out dilatation of heart, the incidence of every cardiac lesion in dementia precox is greater than the incidence of the corresponding lesion in manic-depressive insanity.

4. The incidence of individual heart lesions is relatively greater in the acute psychoses than in all psychoses combined, except that the relative frequency of hypertrophied hearts in manic-depressive insanity is below the average.

5. This study suggests the desirability of a close clinical study of hearts, pulse and blood tension in the group of acute psychoses.

VIII.

Bacterial Invasion of the Blood and the Cerebrospinal Fluid by way of Mesenteric Lymph Nodes: A Study of Fifty Cases of Mental Disease.

BY E. E. SOUTHARD, M.D., AND MYRTELLE M. CANAVAN, M.D.

(From the Laboratory of the Danvers State Hospital, Hathorne, Mass.)

CONTENTS.

Cultivations of the blood post-mortem.
"Contaminations."
Cultivations from the cerebrospinal fluid.
Conclusions from the work of Gay and Southard.
Parallel cultivations from heart's blood, cerebrospinal fluid and mesenteric lymph node.
Case of cultivation of B. typhosus from mesenteric lymph node and cerebrospinal fluid (blood negative).
Direct spread of bacteria in lymphatic system to regional lymphatics of spinal cord possible; route by the blood stream easier to establish in present state of knowledge.
Technic.
Growths obtained from the three sources (tables).
No evidence of fresh post-mortem invasions at successive intervals post-mortem (table).
Proportions of cocci and bacilli recovered from the three sources (tables).
Colibacillosis.
Atria for B. coli and staphylococci in this series.
The cultivations represent invasions, not necessarily infections.
Possible fate of bacteria reaching lymph nodes.
Infection *vs.* invasion.
Reduction of amount of lymphoid tissue in insane hospital material.
Low spleen weights.
Number of positive cultures in our series of mesenteric lymph nodes biased by (*a*) selection of large nodes, (*b*) nature of cases (15 dysenteric, etc.).
Colibacillosis and "soft brains."
Summary.

The interest which attaches to the *cultivation of bacteria from the blood post-mortem* is scarcely less than that which attaches to similar cultivations during life, since the post-mortem bacteriology can be controlled by anatomical and histological data. Although the question of post-mortem or agonal invasion of the blood is still a moot question, which no further accumulation of routine data seems likely to resolve, it has seemed possible to supplement the blood cultivations by parallel cultivations from other regions of the autopsied body and to draw important conclusions therefrom with respect to the spread of bacteria in the tissues, whether that spread takes place *post-mortem* or *ante-mortem*.

The chance that a *pure* culture from the blood is a true "contamination" in the sense in which bacteriologists use the term is at the outset slight. That improbability increases in the event that the same organism is grown in pure culture from other parts of the body, unless, indeed, the blood be so filled with a single organism that no organ or lesion is likely to escape invasion. In the latter event, viz., the event of a colossal invasion of the body by some organism which perhaps outgrows every other bacterium, the importance and pathogenenicity of the organism must be settled on other and general grounds with due reference to the histopathology of the organs and lesions of the case.

Special interest attaches to positive or negative *cultivations from the cerebrospinal fluid post-mortem*, and the accumulation of routine data from this source in autopsied material is still not rich enough for the purpose of that *control of similar cultivations from the living* which clinical pathology demands. The clinical pathologist has still to disregard various organisms cultivated from lumbar puncture fluids withdrawn during life, unless the organisms conform to well-known types generally regarded as pathogenic.

Since the results of the work of Gay and Southard, which preceded and occasioned the present work, are in the course of publication in the *Zentralblatt für Bakteriologie*, and may not be readily accessible to American readers, the conclusions of that work are here inserted:

1. The results of cultivations from the heart's blood and the cerebrospinal fluid post-mortem in 100 cases of mental disease have been correlated with the histopathological findings (Marchi impregnations of the spinal cord at three levels) and the clinical histories, having special reference to a history of terminal disease over or under four days' duration (regarded as a period in which typical Marchi alterations might ensue).

2. The bacteria were cultivated upon agar plates inoculated with 1 to 1.5 ccm. heart's blood and others with the same amount of cerebrospinal fluid. The cerebrospinal fluid was removed from the third ventricle through the infundibulum, severed at its origin.

3. Forty-one per cent of our heart's blood cultures remained sterile (cf. Gradwohl, 22%; Otten, 42%; Simmonds, 48%).

4. Twenty-eight per cent of the cerebrospinal fluid cultures remained sterile.

5. Under the conditions of our laboratory, the statistics show that there is no significant difference in the percentage of positive cultures from either source at varying hours post-mortem and that the danger of contamination must be limited to a brief interval after death.

6. Our findings point definitely, if indirectly, to the intravital significance of the bacteria found, despite the fact that in no particular instance is the chain of evidence complete.

7. Since the same bacteriolytic substances are found in blood serum both before and for some time after death, there is no reason for supposing that bacteria can grow better post-mortem.

8. We now show that bacteriolytic substances are absent in the cerebrospinal fluid, so that there appears to exist therein no extracellular mechanism for the disposal of bacteria.

9. The facts just stated (7 and 8) may account for the higher percentage of organisms in the cerebrospinal fluid.

10. Among the facts concerning the incidence of bacterial forms are these: Cocci were found in the blood in 26 cases, in the cerebrospinal fluid in 34 cases; streptococci, blood 8 times, cerebrospinal fluid twice; pneumococci, blood 3 times; B. coli-aerogenes group, blood 11 times, cerebrospinal fluid 25 times; B. proteus group, cerebrospinal fluid 7 times.

11. The absence of diphtheroid organisms from our series is remarkable, since in previous years cultivations at the Danvers Hospital had yielded such organisms in several cases.

12. Cultivations from 13 general paretics are listed. In the positive cases, cocci prevail.

13. Nine bacteriologically negative cases are listed.

Reasons are adduced for certain histopathological changes, possibly independent of bacteria, in these cases.

14. Ten cases which failed to show specified histopathological changes are listed, from which it appears that B. coli is not found associated with such cases unless the terminal disease happens to have been brief. On the other hand, cocci are frequent findings in this group.

15. Thirty-one cases which had terminal symptoms less than four days in duration are listed; 29% of these failed to show spinal cord degenerations by the Marchi method (as against 10% in the total series).

16. Of 10 cases selected as showing most numerous spinal fatty degenerations (diffusely scattered blackenings in white and gray matter), 9 showed B. coli communis either in heart's blood or in cerebrospinal fluid, or in both, and 8 in large numbers.

17. Of 18 cases yielding 40 or more colonies of B. coli communis from one or each source, 8 showed extreme degrees of Marchi degeneration, 5 relatively severe changes (intraspinal and intraradicular) and the 5 remaining cases showed considerable intraspinal change.

18. Of 13 cases showing generalized softening of brain tissue (general encephalomalacia), 10 yielded B. coli communis.

19. A definite relation must be assumed to exist between B. coli communis or its toxins and nerve fiber degeneration.

Our Danvers Hospital data concerning *parallel post-mortem cultivations from the blood and cerebrospinal fluid*, coupled with the modern suspicion that the blood is a frequent atrium of infection for the nervous system, led us to undertake further cultivations from the lymphatic system. We hoped to add evidence concerning the possible route of organisms toward the meninges.

We regarded those cases in which there are infective thrombi or other infective lesions opening directly into the blood system, and those cases in which generalized blood infections have been thoroughly demonstrated to occur (e.g., lobar pneumonia), as furnishing adequate data for the hypothesis of such atrium for infection of the meninges. But, barring such easily comprehensible methods of entry, certain current conceptions as to the part played by invasions from the intestinal tract seemed to give point to an investigation of the lymphatic apparatus lying between the intestines and the blood.

Of course, the invasion of the mesenteric lymph nodes or of the mesenteric lymph nodes and the blood by organisms from an injured or ulcerated mucosa almost goes without saying at the present day. Take *typhoid fever*, for example. Typhoid bacilli may be cultivated from the lumen of the intestine, from the intestinal wall, from the mesenteric lymph nodes, from the blood and from various organs. The well-known data concerning early positive blood cultures in typhoid fever in fact suggest that before the establishment of ulcerations typhoid bacilli may penetrate the mucosa and pass by way of the mesenteric lymph nodes into the blood.

Very early in our *systematic cultivations from the blood, cerebrospinal fluid, and mesenteric lymph nodes*, we came upon an interesting confirmation of the idea concerning typhoid fever just stated. As E. T. F. Richards and one of the writers have already communicated, we were able to cultivate from the mesenteric lymph nodes and cerebrospinal fluid of a case of general paresis the typhoid bacillus in pure culture. This was the more remarkable since the intestinal mucosa showed no ulceration or sign of acute lesion. All that the intestinal tract showed was a certain thinning out or atrophy, such as is not uncommonly found in general paresis, and which very probably would favor the passage of bacteria into the lymphatics. The mesenteric lymph nodes of the case showed some reaction to their infection, visible even in the gross. Now the blood contained no typhoid bacilli. The natural supposition is that, of those bacilli which passed into the blood, the majority were speedily killed, but that some effected lodgment in the meninges and there grew. The exudate which characterizes the meninges and the walls of the cortical vessels in general paresis offered a good soil for the growth of the bacilli. Just so, purulent or exudative lesions elsewhere may acquire the typhoid bacillus, which proceeds to grow abundantly and yield the impression of having caused the lesions *ab initio*. In the case in question, it was not difficult to separate histopathologically the lesions of general paresis from the polynuclear leucocytic exudation superimposed by the typhoid bacillus.

In certain other diseases, septicemia may rarely or never occur, as in bacillary dysentery, which may show Shiga bacilli in the intestinal lumen, in the intestinal wall, in the mesenteric lymph nodes and perhaps occasionally in the liver, but rarely or never in the blood or cerebrospinal fluid. Either these organisms do not find proper food in these latter loci, or, what is perhaps more likely, they are killed there by bacteriolytic substances.

Another route from the lymphatic apparatus to the meninges should be mentioned. There is a possibility that the lymphatics of the spinal column and of the spinal meninges may be directly invaded, through lymphatic intercommunications, from the mesenteric lymph nodes and thus from the intestinal lumen, but anatomical, histological and embryological knowledge of the regional lymphatics of the spinal cord is still quite inadequate to cope with this problem, even as an hypothesis. This field should, however, not be excluded from research. It should be observed, in passing, that many of the patients who have lain for long periods in the dorsal decubitus must surely have undergone very little massage of their lymphatics in this region, so that the spread of bacteria against the proper direction in these lymphatics cannot be excluded.

In order to pave the way for more intensive work as to lymphatic spread of organisms, we have undertaken to cultivate organisms from the blood, cerebrospinal fluid and mesenteric lymph nodes in a series of 50 unselected cases. The cases have not all been consecutive because the exigencies of other work in the Danvers Hospital laboratory have made it at times inconvenient to carry out this special work.

The cultivations have been made between November, 1907, and September, 1909, that is, during the pathological services of Drs. E. E. Southard (till May, 1909) and H. M. Adler. The bacteriological work was under the immediate care of Dr. E. T. F. Richards until September, 1908, and thereafter was done by Dr. Myrtelle M. Canavan and in part by Dr. Anna H. Peabody. The work has been almost uniform in method which was largely systematized for the institution during Dr. F. P. Gay's connection as bacteriologist (August, 1906, to September, 1907).

The detail of the methods employed for the blood and the cerebrospinal fluid has been described in a previous article. The cultures from the mesenteric lymph nodes have been made, after searing the surface and section with a sterile knife, by collection in a stiff platinum loop of one or more loopfuls of node material. (The dryer the node, the more loopfuls were taken.) *A priori*, it might not be supposed that a rich seeding of the agar plates would be procured by this method. A considerable proportion of positive cultures was obtained, as is described in detail below. But the evidence of bacterial content is qualitative rather than quantitative.

Growths of some sort were obtained on the plates as follows:

	Cases.
Heart's blood,	41
Cerebrospinal fluid,	43
Mesenteric lymph nodes,	39

Of these growths, a few were obvious contaminations, so that the table should better read as follows:

	Cases.
Heart's blood,	41 − 4 = 37
Cerebrospinal fluid,	43 − 2 = 41
Mesenteric lymph nodes,	39 − 1 = 38

It seems best to calculate the percentage of positive cultures, omitting the contaminated cases from the denominator, whereupon the table stands as follows:

	Per cent. positive.
Heart's blood,	80
Cerebrospinal fluid,	85
Mesenteric lymph nodes,	78

Growths from one region and not from the other two were obtained as follows (contaminations placed after minus sign and reckoned out of the denominators for percentages) —:

		Per cent.
Heart's blood,	1 − 0 = 1	2
Cerebrospinal fluid,	1 − 0 = 1	2
Mesenteric lymph nodes,		0

Growths from two regions and not from the other were obtained as follows (contaminations treated as above) —:

		Per cent.
Heart's blood and cerebrospinal fluid,	8 − 3 = 5	10
Heart's blood and mesenteric lymph node,	3	9
Cerebrospinal fluid and mesenteric lymph node,	8 − 1 = 7	17
Growths from all three regions,	29 − 5 = 24	55

These figures show the statistical chance of obtaining organisms from these regions with ordinary precautions. The most interesting theoretical matter which they seem to demonstrate is that, where cultures are taken from these chosen regions, the cerebrospinal fluid is the most likely to show organisms, and the blood and mesenteric lymph nodes area about equally likely to show them, though less often than the cerebrospinal fluid. The conditions, whatever they are, which permit invasion of these regions and maintenance of organisms there favor the cerebrospinal fluid and the lymph nodes as against the blood.

In the interpretation of these results, the number of hours post-mortem comes into question. The previous work in this laboratory had tended to show that, after an initial period of two hours post-mortem, there could not be demonstrated, statistically at least, any tendency to fresh invasions of the blood and cerebrospinal fluid.

TABLE I.

Percentage of Cases Giving Positive Cultures.

Hours post-mortem.	Number of cases.	Heart's blood Per cent.	Cerebrospinal fluid. Per cent.	Mesenteric Lymph Node. Per cent.
0−2	4	75	75	75
2−4	4	75	100	50
4−6	4	100	100	100
6−12	8	88	75	88
12−24	17	88	82	76
24−48	11	73	100	100
48+	2	100	50	50

The cultivations are so rich from all sources in this series that comparisons of the result of cultivation at varying intervals post-mortem are difficult. In any event, however, there are no significant differences according to the period after death, and the conclusion of the former paper (Gay and Southard) is maintained that. if the invasions are *post-mortem*, they must in the vast majority of instances occur in the first two hours or so after death, that is, when much of the body is histologically alive.

The organisms occurred in the proportions shown in Table II (page 205).

The cerebrospinal fluid leads the other sources in the proportion both of cocci and bacilli found. This fact is wholly consistent with former results and with the fact formerly adduced that the cerebrospinal fluid contains no bacteriolytic substance. With quite proportionate seeding, it is probable *a priori* that this relation will hold.

The same order (1, cerebrospinal fluid, 2, heart's blood, 3, mesenteric lymph node) holds for the general group of organisms found in pure culture (i. e., 1, 24; 2, 21; and 3, 16).

If we consider the cocci alone, however, the blood leads with 20 (cerebrospinal fluid, 17; mesenteric lymph node, 10). An inspection of the data shows that this predominance is largely due to the albus. Removing the albus from all three sources, we arrive at: Cerebrospinal fluid 10; blood, 10; and node, 6.

We must be cautious in drawing conclusions

from these figures, not only because of their size, but because of uncontrollable variations in technic. It seems to us, however, that elaborations in our technic can do no more than swell the proportion of positive cultures[1] and, although the relations may be altered by further work, the general fact of frequent bacterial invasions of all these three sources must be accepted.

The occurrence of B. coli communis in 7 cerebrospinal fluids and 6 mesenteric lymph nodes as against only once in blood is surprising, although in general consistent with former results. On the basis of the older work, these cases of colibacillosis should show more effects in the nervous system than, for example, cases of staphylococcosis. The general features are as shown in Table III, page 206.

The analysis of these cases of colibacillosis reveals certain facts highly consistent with the hypothesis of B. coli infection of the blood through the lymph system and infection of the meninges by way of the blood. The single case of colibacillemia without cerebrospinal or mesenteric lymph node invasion most probably secured its infection from a cystitis. (A series of appropriate lymph-node cultures in such cases is being made.) Of the purely lymphnodal invasions, two were cases of bacillary dysentery, in which the atrium for lymph node invasion by B. coli is obvious, and the other case showed many fibromyomata of stomach and duodenum with hemorrhages and an acute hemorrhagic pancreatitis. Two of the three combined lymph node and cerebrospinal invasions yield obvious atria, but the third (1226) is less clear (bilateral adrenal tuberculosis). The purely cerebrospinal cases, showing cystitis, pyelonephritis and acute ileitis respectively, are consistent, save that the third case (1257) should apparently have shown B. coli in the slightly enlarged mesenteric lymph nodes.

[1] e.g. more pneumococci, B. influenzæ, etc.

A similar analysis of the cases of staphylococcus invasion has been made, but will not be presented in detail. Cases 1240 (abrasions), 1252 (decubitus), 1220 (septic hand), 1256 (bruises), already mentioned under colibacillosis, sufficiently illustrate the kind of atrium of infection which these cases show.

Of course, we do not wish to convey the impression that we regard all these instances of staphylococcosis as genuine instances of *infection*. Possibly staphylococcus albus lives in many loci for a time without noteworthy effect. The effect of bacillus coli communis is also problematical, although the paper of Gay and Southard presented certain evidence looking to its lytic effect upon nerve elements. These cultivations should be regarded, on present evidence, as *due to invasions, not necessarily to infections, of the loci tested.* The evidence for the truly parasitic nature of these bacteria is for the present no stronger than for their saprophytic character. The method of invasion by saprophytes may not be unlike the method of infection by parasites.

Entry into lymphatics, collection and destruction or survival in lymph nodes, entry of survivors into the blood stream, destruction or survival in the blood stream, lodgment of occasional bacteria in remote loci like the meninges, may be the frequent history of micro-organisms in the body. Bacteriolytic substances in lymph, lymphnode tissue, or blood stream tend to rid the body of the invaders. Those that effect entrance into the cerebrospinal fluid are apparently not ordinarily

† Doubtful bacteriologically.

subject to directly lytic action and, when they die, die of other causes

In attempting to solve the important *question as to the infectious versus the invasive character of the recovered organisms*, we must divest ourselves of preconceived notions as to the non-significance of certain organisms and the significance of others. To take but one example, staphylococcus albus is in some laboratories regarded forthwith as a contamination, especially when recovered from the blood in life or from the cerebrospinal fluid. The reason for so regarding this organism is grounded perhaps in distrust of technic and in established facts concerning the incapacity of the organism to kill or seriously injure laboratory animals. It seems to us that it might be wiser to accept such findings (with all due precautions concerning technic, repetition of cultivations, purity of cultures and post-mortem confirmation) as evidence of invasion at least, if not of infection. Such parallel cultivations as we have been making should lay a foundation for explaining these findings. Perhaps many otherwise normal and healthy persons may at times show bacteriemia or even cerebrospinal fluid invasions, due to penetration of bacteria beyond the lymph node defences. And in terminal exhaustions, such as we frequently find in the insane, it would seem that these invasions are almost the rule.

Besides those epidermal and intestinal atria which are due to actual molar solution of continuity in the tissues (trauma, hemorrhage, etc.), illustrated in Table III, we must also remember the reduction of lymphoid tissue in the intestinal mucosa seen in several kinds of insanity, as well as alterations possibly characteristic of lymphoid tissue generally in these cases.

There is, for example, a surprising reduction in the volume of spleen tissue in the great majority of our Danvers Hospital cases, which is fairly well indicated by the spleen weights. Thus, in the present series, only three spleens ran 200 gm. or over (1284, 200 gm. an aureus septicemia in a general paretic; 1239, 205 gm. an aureus septicemia in an arteriosclerotic dement of eighty-three years; and 1292, 260 gm. with blood and node cultures contaminated and cocci of unidentified character in cerebrospinal fluid, a general paretic with pyelonephritis). Even including these three cases, the average spleen weight for males (28 cases) was 111 gm, and the average for females (20 cases noted) was 84 gm. Thirteen of the male spleens and 15 of the female spleens ran 100 gm. or less.

The problem is certainly not confined to lymphoid tissue as the livers are also under weight (male average of 28 cases, 1247 gm.; female average of 20 cases, 1113 gm.). The hearts, meantime, average, male 277 gm. (29 cases); female 225 gm. (20 cases), or, with the elimination of 4 male cases having hearts weighing over 410 gm. the male average is 247 gm. (Female maximal heart weight was but 365 gm.) The kidney weights were: Male, average 242 gm. (29 cases); female, average 213 gm. (18 cases).

As far as statistics carry us, then, it would seem

that the lymphoid tissue is subjected to the greatest alteration in these cases; that the livers are also somewhat reduced in bulk.

The conditions in the intestinal tract deserve especial histological study and may explain the frequency of mesenteric lymph node invasions. Before undertaking this, however, it seems advisable that similar bacteriological studies to ours with insane hospital material should be carried out in some general hospital laboratory.

Our selection of mesenteric lymph nodes for special bacteriological study was governed not only by the general suspicion now entertained by pathologists as to the frequency of intoxication *via* the intestines, but also by the statistical frequency of mesenteric lymph node alterations in Danvers Hospital material. From the earliest Danvers records down, the mesenteric nodes have been more frequently noted as subject to lesion than have any other nodes, with the possible exception of the bronchial nodes (so frequently tuberculous).

In our series, enlargement, or enlargement with softening, or enlargement with infection, was noted in over half the cases. A remarkable feature of the findings was that very frequently only one or more nodes in a given group showed such microscopic effects. Such altered nodes were constantly chosen for culture. Moreover, if no palpable nodes could be found, cultures were omitted, so that doubtless our series is biased not a little in the direction of positive cultures.

The preponderance of cases in which isolated nodes and not the whole regionary system are involved leads to the conception of local penetration of bacteria through specially injured surfaces. Here again data from the general hospitals are needed. Multiple cultures from different lymph node systems, and from different nodes of the same system, will throw light on this problem, particularly if the surfaces and organs drained be carefully examined.

Thirty of the 50 cases gave signs of reaction on the part of the intestine, varying from local injections up to definite hemorrhagic and ulcerative conditions. Fifteen cases were, in fact, cases of our epidemic of dysentery. Scybala were found in many more, but without observable reaction thereto. Again, without intending it, we have doubtless biased the results in the direction of positive mesenteric lymph node cultures through the nature of the material. In the absence of the atria afforded by dysenteric ulcers, and in the absence of bias due to the selection of enlarged nodes for culture, a much lower percentage of positives might be obtained.

Bearing this bias of our material in mind, let us consider the cases in the light of the indication afforded by the previous hundred cases, viz., that colibacillosis tended to coexist with soft brains.

Colibacillosis of various distribution occurred in 9 cases (see table above for statistical data).

The case of cystitis with colibacillemia failed to show a soft brain. Two of the cases of purely cerebrospinal colibacillosis (1252 and 1257) showed generalized reduction of consistence of the brain, whereas the third case (doubtful bacteriologically) failed to show a soft brain.

The cases of combined lymphnodal and cerebrospinal colibacillosis were unsuitable for the display of "soft brain," since all three were extreme examples of sclerotic conditions of the central nerve substance which always mask the soft brain. No. 1220 was an organic dement of eighty-five years with cysts of softening and generalized gliosis. No. 1226 was a juvenile general paretic with generalized induration of the brain, emphasized focally by unusually hard gyri. No. 1285 was an epileptic idiot with congenital anomalies and probably some acquired induration of the brain.

One of the two cases of purely lymphnodal colibacillosis showed a brain slightly softer in some places than in others, frankly indurated portions. Another gave no sign of reduced consistence. A third showed soft brain (1265).

Analyzing from the other side, "soft brains" were described in 7 cases. 1252, 1257, 1265, have just been mentioned; 1264 showed a slight general reduction of consistence of the brain, and all three sources showed certain unidentified cocci.

No. 1278's brain resembled 1264's and showed infection of all three sources with a particular bacillus now being especially studied. No. 1336 showed variations in the consistence of different parts of the brain, and all three sources yielded another bacillus which is being especially studied. No. 1304 showed certain softer places in the cerebrum and a remarkable local softening of the spinal cord; blood and fluid were sterile, node contaminated.

The results of this study are in some respects confirmatory of the former study. Doubtless the "soft brain" can be produced in several ways. Bacillus coli communis is at least prominent among the bacteria associated with the condition. The relation in our total series is to be subjected to special study.

SUMMARY.

I. Following the same technic chosen by Gay and Southard for their study of the post-mortem bacteriology of the heart's blood and cerebrospinal fluid in 100 cases of mental disease, the writers have examined 50 further cases from the same source (Danvers State Hospital, Massachusetts), with the addition of cultivations from mesenteric lymph nodes.

II. The material was unselected, save (1) that cases without readily palpable nodes were not examined and (2) that 30 of the 50 cases gave macroscopic signs of intestinal disease of greater or less severity (15 from an epidemic of bacillary dysentery).

III. As in the former work, there were no detectable differences in the proportion of bacteria grown at different intervals post-mortem. (Table I.)

IV. Positive cultivations (excluding a few frank contaminations) were obtained in (*a*) cerebrospinal fluid, 85%; (*b*) blood, 80%, and (*c*) node, 78%.

*Unsuspected during life. †One of these unsuspected during life.

V. Growths from all three regions were obtained in 55%.

VI. Growths from two out of the three regions were most frequently obtained in cerebrospinal fluid and lymph node (17%), a fact which may be interpreted as due to an effective bacteriolysis in the blood (compare previous article).

VII. Table II gives the incidence of various organisms found: *Cocci* in the blood, 20 cases; in the cerebrospinal fluid, 22 cases; and in the lymph node, 16 cases (staphylococcus aureus in these sources, 5, 6, and 3 cases respectively; streptococci, 2, 1 and 0 cases); *bacilli* in 1, 8 and 10 cases in the respective sources.

VIII. The colibacilloses are especially interesting in the light of the relation between colibacillosis and "soft brains" suggested by the results of Gay and Southard. Our one case of colibacillemia failed to show a "soft brain." Two of three cases of pure cerebrospinal colibacillosis yielded "soft brains," and the third (doubtful bacteriologically) was negative. The three combined lymphnodal and cerebrospinal invasions were unsuitable, being all three instances of extreme sclerosis. Two of the three pure lymphnodal colibacilloses showed "soft brains" (one only in non-sclerotic parts) and the third was negative. Thus four out of seven cases suitable for such display showed palpably soft brains in association with colibacillosis.

IX. Analyzing in the other direction, there were seven "soft brains" in the series, three of which showed colibacillosis; two, infection with special pathogenic bacilli (under special study); one, contamination of node; and one, generalized invasion with certain unidentified cocci.

X. Appropriate atria for the invasions and infections are demonstrable in the majority of instances.

XI. Our findings seem consistent with the hypothesis that in the terminal exhaustions of the insane bacterial invasions are almost the rule. Perhaps otherwise normal and quite healthy subjects may, more often than hitherto suspected, show bacteriemia or even cerebrospinal fluid invasions.

XII. The intestinal wall is a leading atrium, for such invasions, an atrium perhaps the more penetrable by reason of atrophic processes frequently displayed. The livers and especially the spleens are much underweight in the majority of our cases.

XIII. Mesenteric and bronchial lymph nodes lead the other nodes in proportion of diseases displayed in the total Danvers collection. Often only one or two of the lymph nodes in the group exhibited gross lesions.

IX.

Bacillary Dysentery at the Danvers State Hospital, Massachusetts, Subsequent to the Epidemic of 1908.

By Myrtelle M. Canavan, M.D.,
Assistant Bacteriologist, Danvers State Hospital.

The results of our study of bacillary dysentery at the Danvers State Hospital during 1908 brought out certain facts which made a study of post-epidemic, or (more accurately) *endemic*, conditions at the hospital imperative. The study of endemic conditions is peculiarly desirable since the experience of English Continental and American dysentery workers indicates that the importance of asylum dysentery is rarely recognized. The part it plays in the cause of death is often masked by other assigned causes, and institution men are still met with who take the summer incidence of more or less dysentery as a matter of course.

It will be remembered that in the former report we had a choice between a probable introduced carrier and the existence of intramural carriers as the origin of the epidemic. The present work demonstrates the persistence of cases virtually throughout the total period of eighteen months (see below).

The validity of several conclusions from the previous work depends upon the continuance of intensive work on the same lines as before, and the present report contains tables similar to the former ones.

The hospital was free from cases of dysentery four months of the eighteen here recorded, namely, December, 1908, January and February, 1909, and February, 1910. The first fatal case in 1909 was in March, E. H. No. 14015, on a male ward, J2; in the same month two cases occurred on B2, a female ward, widely apart from this, and one case each in wards J1 and H1, thus ushering in the continuous line of cases until February, 1910. During the early summer months the cases were frequent and the mortality high, but in the months of August and September reached epidemic numbers in morbidity, with a decrease in percentage mortality, fell again in October and November, and were absent in February, 1910. (See Fig. 1 and Table 1.)

The hospital during the entire summer was overcrowded, the census reading 1504–1515, with ostensible accommodations for only 1250. Cases of ward transmission by contact, always difficult to avoid, were, under these circumstances, more or less to be expected, according to Osler's dictum of "Food, Fingers and Flies" as agents of transmission in infectious diseases. Effort was made to screen a portion of the hospital at this time and no doubt prevented cases. In future, the efficacy of screens in kitchens, basements and halls, fireplaces, food-cars, etc., should be thoroughly tested.

Middleton Colony was relatively free from dysentery both during and after the 1908 epidemic. Here 250 women are segregated, none of whom had dysentery (1 of 5 male patients living there as helpers had an attack). The transfers from the

main hospital to this colony do not include disturbed, untidy or bed patients. The only possible point of contact with infected material is through the laundry, in this case not a nidus of infection. In the separate buildings where few patients were congregated, which are well ventilated and have individual dining rooms, the disease is limited to one or two cases in a season. On this point compare Table I, Tuberculosis Buildings,

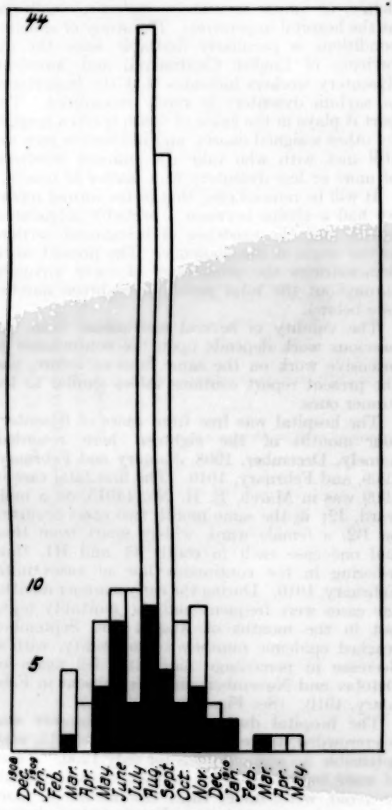

FIG I..

Middleton Colony, Grove Hall, Dayton Hall; but, where bed cases and untidy patients are closely associated, opposite conditions prevail; see wards A2 and B2, I3 and J3, Table I.

It cannot be too strongly emphasized that other infectious diseases need isolation, efficient care and open-air treatment as well as tuberculosis. Little thought is given to dysentery as a terminal disease. It is not required to be reported to the state boards of health, and it is accepted as an annual scourge and cause of death with no real effort at prophylaxis and variety of treatment, especially in hospitals and asylums.

DYSENTERY AT THE DANVERS STATE HOSPITAL, FROM DEC. 1, 1908, TO JUNE 1, 1910.

REMARKS AND CONCLUSIONS.

1. The post-epidemic conditions in bacillary dysentery at the Danvers State Hospital have been specially studied, and the disease shown to be virtually endemic there (no cases in four of the eighteen months studied).

2. As predicted in the former report, though flies may be responsible for extensive *epidemic* spread of dysentery, the maintenance of *endemic* dysentery is dependent upon another factor. This factor is presumably the bacillus-carrier. (see articles for corroborative evidence.)

3. The immunity of our colony of about 250 female patients (Middleton Colony) as compared with the hospital at large is even more striking in 1909–10 than in 1908, and emphasizes the fact that clothes infection *via* the common laundry can be excluded as an epidemiological factor. Water, milk and food, *except as secondarily infected* continue to be excluded as factors, as well as subsoil disturbances.

4. The peculiar May incidence of dysentery at the Danvers State Hospital, which was brought out strikingly in Ryder's report (Fig. IV, 1908

Report) on the basis of ten years' data is not found constantly, since in 1909 and 1910, May was exceeded by June in number of cases.

5. The data appear to offer a powerful argument for the pavilion or cottage system, as opposed to the massive block system of insane-hospital construction.

GENERAL STATISTICAL DATA.

	Epidemic 1908.	Endemic December, 1908-June, 1910.
Danvers State Hospital population (approximate)	1592	1687
Cases of dysentery	156	142
Percentage of morbidity	9.8	8.4
Fatal cases of dysentery	36	42
Percentage mortality in dysentery cases	23.1	29.5

X.

Organisms Recovered From Dysentery Cases Studied Bacteriologically December, 1908, to June 1910, at the Danvers State Hospital, Massachusetts.

BY MYRTELLE M. CANAVAN, M.D.

The total number of stools studied during this period was 55; scrapings from ulcers of autopsy material, 13. From the stools, the B. dysenteriæ was recovered in 29 instances; from the autopsies in 6; In 68 attempts, there were recoveries of B. dysenteriæ in 35 instances. A bacillus probably of the fowl cholera group was recovered 23 times. There were 10 failures (B. coli, cocci, etc.).[1]

Finding the dysentery bacillus in only 6 out of 13 autopsies is due to fewer (3 to 10) plates being employed, having no second specimen, overgrowth of the colon bacillus, number hours post-mortem, etc. Twenty-seven of the remaining 28 cases were atypical clinically, the attack ushered in by five or six bloody movements, with rapid recovery from the symptoms, and the stools submitted on the second and third day were frothy liquid. One case was typical and three stools were examined with no success in isolation of the B. dysenteriæ. One case was of twenty years' duration, a history so unusual that a brief note is here given.

M. B. No. 14423. A farmer lad living in Maine, aged twenty years, began suddenly to have diarrhea, which persisted despite treatment year

[1] Too many thanks cannot be expressed to Mr. N. Kinsman in appreciation of the faithful and unfailing uniformity in cleaning the multiplicity of tubes and plates used in this investigation.

after year, losing weight in the summer, when the symptoms were most marked, regaining in the winter when the diarrhea abated. After fourteen years of this alternation he began taking Squibb's diarrhea mixture in dram doses, three times each day, with gradual increase, until after six years he came as a voluntary patient to this hospital, fearing he was a morphine habituate. At this time he was consuming 4 oz. of the mixture in three days and still having six or seven movements, with tenesmus. The stool examined showed abundant colonies of a bacillus of the fowl cholera group, and his serum agglutinated stock organisms of the Shiga and Flexner types in dilutions of 1 — 300 and — 250 respectively.

TECHNIC.

The technic was essentially the same as used by Richards, Peabody and Canavan, in the "Report of an Epidemic or Bacillary Dysentery at the Danvers Hospital in 1908," as described by Duval in the "Studies from the Rockefeller Institute, 1904," with the adoption of Shorer's seven-plate method in a few cases, Hiss' semi-solid media for the simultaneous detection of motility and gas production and the inoculation with the organism recovered of the sugars, mannite, maltose, lactose, saccharose, galactose and dextrin (Hiss' litmus sugar serum water). This gave interesting results coupled with the agglutinations: Thirteen did not ferment any of the sugars, 8 fermented lactose alone; these agglutinated Shiga's antidysenteric serum in 1: 200 — 1: 2000 dilutions. The remainder of the organisms showed selective fermentation action in the sugars and somewhat higher agglutinative powers with the Flexner-Harris strain of anti-dysenteric serum.

In no case did the blood, the mesenteric lymph nodes or the cerebrospinal fluid from the autopsied cases show the B. dysenteriæ.

Danvers State Hospital case numbers from which B. dysenteriæ were recovered: 14884, 15102, 15004, 7965–14245, 10098–10580, 14974,14403, (1332), 14275, 15169, 14935, 13642, 13412, 14546, 14870, 14747, 12171–12692, 14695, 14899, 14071, (1326), 14989, 14668, 11023, nurse, 11591–11905, 14849, 13288–14845, 14349, attendant, 14291, 14253, (1332), 14248, 14724, (1341), 14989 (1342),14774, (1343), 14403.

Danvers State Hospital case numbers from which a bacillus of fowl cholera group was recovered: 13759, 14423, 14108, 14496, 15392, 14120, 14971, 12075, 13524, 14758, 15167, 14681, 10881, 7452, 14408, 14255, 14989, 8471, 14520, 14530, 14309, 14770, 14253.

CONCLUSIONS.

1. The endemic cases were of fermenting (14) and non-fermenting (21) types, whereas the epidemic cases of 1908 were mainly due to the Shiga type (13 as against 1 fermenting).

2. The scant fermenters (lactose only) are agglutinated by anti-Shiga serum as well as the non-fermenters.

3. Atypical cases contain an organism probably of the fowl cholera group.

4. The blood, cerebrospinal fluid and mesenteric lymph nodes did not contain the B. dysenteriæ.

XI.

The Persistence of Agglutinins for B. Dysenteriæ in Danvers Hospital Cases, together with a Series of Conglutination Tests.

BY MYRTELLE M. CANAVAN, M.D.

The agglutination reactions begun in 1908 were continued through this period and the results given in Table X. It will be noticed that Nos. 73, 90, 91, 99, 107 and 116 show continued reappearance of the reaction, with an interval of negative results: Transfer of type agglutinations occur in Nos. 73, 90 and 116. In no case did the patient suffer relapse.

As in two cases mentioned by Richards, Peabody and Canavan in the 1908 report (note under Table X) a hint of the pro-agglutinoid zone appears in the reactions of 63 and 116 against Shiga and Flexner respectively in April, 1910.

One case, 116, shows a tendency to periodic appearance of agglutinins (Flexner).

In 12 cases (see Table) the patients' sera were first used in the ordinary agglutination reaction, and later the conglutination reaction of Bordet and Streng was tried simultaneously, with a repetition of the agglutination with the Shiga, Flexner, and B. coli organisms. It was seen to be more delicate than the agglutination (see Nos. 9, 15, 17 Table) in some cases, especially for B. Flexner and B. coli, but curiously not for B. Shiga.

XII.

Mannite- and Non-mannite-fermenting Organisms in a Case of Dysentery, Complicated by Hemorrhagic Endometritis Probably due to a Third Organism.

BY MYRTELLE M. CANAVAN, M.D.

A woman, V. D. 14003, admitted to the Danvers State Hospital, July 10, 1908, sixty-one years of age, passed uninfected through the epidemic which was at its height shortly after her arrival and died on the twelfth day of passing bloody stools, in June, 1909.

She was thought to have had a cerebral hemorrhage two years before coming to this hospital, at the age of fifty-nine, and her father, a heavy drinker, had died of the same lesion at the age of sixty-nine, but her mother is still alive aged eighty-three or eighty-four years.

Typhoid fever was contracted at thirteen years, after which several abscesses over her back developed; beside this and severe headaches her previous personal history is negative.

She was married at twenty-two years and four children were born, three died young. The climacteric occurred at forty-six years. From the time her husband left her, at thirty-five years, until her illness at fifty-nine, she kept a boarding-house and worked very hard to provide a living, and after the "shock" was a threatening and irritable woman, with definite dementia and apprehensive ideas, growing more feeble, restless, noisy and untidy.

The terminal illness lasted twelve days, preceded by a simple diarrhea, during which time her serum did not agglutinate the stock cultures of B. Shiga and B. Flex-

* Serum at autopsy.
† cgl. = conglutination.

ner. After the frequent bloody stools began it was difficult for her to take nourishment, and she succumbed from exhaustion and toxemia. A stool submitted for examination on the third day yielded two types of the B. dysenteriæ, a mannite-fermenting and a non-fermenting organism. The autopsy was performed by the writer fifteen hours after death and the protocol follows: Age sixty-one. Body of a very emaciated, slender, white female, 160 cm. in length. The left leg is in extreme degree of contraction and the body is in right lateral decubitus with semi-flexion of right leg. Bed sores over sacrum and right trochanter major. Rigor mortis present. Lividity present. Buttocks excoriated. No edema. No bruises. Right pupil, 2.5 mm.; left, 3.5 mm. Teeth: Incisors mere stumps; others seen are foul.

Ventral section: Panniculus scant and of deep orange color and dry. Muscles pink-red. Spleen free; appendix normal. No enlarged lymph nodes seen. Some bloody fluid in pelvis. Intestines injected, especially ileum. Omentum sparse in fat. Bladder distended. Uterus dark in color. Tubes inflamed. Diaphragm arches to fourth interspace on right; to fifth rib on left.

Thorax: Mammary arteries not unusual. The lungs meet in median line, are voluminous and anthracosed. Few adhesions at apices.

Heart: Weight, 195 gm. Cylindrical in shape. Epicardium not notable. Muscle rather softer than usual.

Measurements: T. V., 12.0 cm.; M. V., 8.0 cm.; L. V., 1.0 cm.; P. V., 6.0 cm.; A. V., 6.5 cm.; R. V., 0.3 cm.

Endocardium not notable except in ventricles, where it is slightly thickened. The arch of the aorta is curiously thickened in plaque-like arrangement and on two are recent fibrinous vegetations, 0.5–1.0 cm. in diameter. Aorta in its entire length sclerosed. A puriform thrombus occupies the entire right common iliac artery.

Lungs: Left lung weighs 440 gm. Nothing of note. Right lung weighs 550 gm. At apex a fibrotic and calcified nodule 2 cm. in diameter; no pus seen. The lower lobe is very irregularly firm to the touch. Section

shows a foul green-brown necrotic cavity measuring 2 x 2.5 cm. in center of the lobe. It contains nothing but detritus. Odor marked. In the surrounding tissue firm yellow-red areas are seen which exude pus on pressure. Section floats in water.

Abdominal cavity. — Spleen: Weight, 100 gm. Measures 12 x 9 x 3 cm. On its anterior capsular surface a distinct ridge 6 cm. long by 2 cm. wide is seen. It is somewhat firmer to the touch. On section it is pyramidal in shape; base at the periphery and extends into the organ 0.5 cm. and is easily differentiated from the surrounding tissue (firm and red) by its uniform resistance and light pink color. The upper pole of spleen seems much darker than the inferior. No Malpighian bodies seen. Accessory spleen 2 cm. in diameter attached to superior pole of kidney.

Adrenals: Nothing of note.

Kidneys: Weight 270 gm. They are small and fatty, capsule is stringy and brown. The fibrous capsule is not adherent, but the cortex wells over the capsule on section. The pyramids, deeply brown-blue, stand out sharply from the pale pink-yellow of the cortex, which is but slightly injected. Here and there is an area sometimes blending with the pyramid and of the same color, which area involves the cortex and is not raised or depressed at the periphery. Pelves normal in appearance.

Gastro-intestinal tract. — Esophagus: Is edematous and the mucosa is a dirty brown in color. The fundal end of the stomach is covered in only by the serous coat and on manipulation to remove it ruptured and spilled contents. In various places the muscularis has disappeared, leaving but the outer coat. The mucosa where present is gray and the content of the stomach black-brown and foul smelling. The blood supply appeared as delicate black tracery.

Duodenum: Normal. Much rich bile staining seen.

Jejunum: Normal.

Ileum: Is thin and deeply prune-colored, though no exudate seen until the cecum is neared, where some gelatinous mucus is seen. The cecum is deeply covered with black material (R, bismuth, gr. 5; q. 1 hr.) and only here and there is seen a red solitary follicle. This condition persists until the sigmoid is passed, where the bowel is then thickened; the mucosa is thrown into deep folds and the summits of the folds are hemorrhagic, with here and there a few frank ulcers not more than 0.5 cm. in diameter. These are shallow, with red edges and irregular contour. Rectum practically free below the valves.

Liver: Measures 22 x 23 x 8 cm. Nothing of note except edges are sharp. Weight, 1,250 gm. Section negative. *Gall bladder* negative.

Bladder is distended with deep dark-colored urine. The urethra measures 1.5 cm. in length. Trigone slightly inflamed.

Vagina: White and smooth. Cervix: Edematous and purple black. Os: Not discernible. Uterus is lined by heavy hemorrhagic mucus, with small polyp at fundal extremity. The right tube is red, convoluted, bent upon itself and attached to the broad ligament, near the horn of the uterus. The left is not as marked, but shows the influence of previous inflammation.

Thyroid: Normal on section.

Head: Hair fine, white and abundant. Scalp and periosteum not remarkable. Calvarium: Well supplied with diploe. Dura not adherent to the skull, but thickened along the middle meningeal vessels. Pia is irregularly thickened over atrophied convolutions in frontal and postcentral regions. The pia is very thin and delicate, but over sulci very milky-white. The pia is lifted from the brain cortex by clear fluid sometimes to the extent of 2 to 2½ cm. The consistency of the entire brain is firm. Pia over cerebellum is thickened. Basal vessels slightly and evenly sclerosed. Much excess of cerebrospinal fluid in fossæ.

Brain weight, 1050 gm.

Middle ears: Right normal. Left drum ruptured and dried. Some fresh hemorrhage around pituitary.

Cord: Pale and soft, welling up when cut.

Anatomical diagnosis. Emaciation, contractures of legs, decubitus, excoriation of buttocks, unequal pupils, teeth foul, slight hemorrhagic fluid in pelvis, distention of bladder, focal adhesive pleuritis, slight ventricular endocarditis, vegetations on sclerosed areas in arch of aorta, puriform thrombus, in right common iliac artery, fatty heart, healed tubercle of apex of right lung, chronic fetid bronchitis, gangrene of lung, infarcts of spleen, acute nephritis, fatty kidneys, thin gastric wall, acute ileitis, slight acute colitis, urethra long, acute cervicitis, endocervicitis, acute hemorrhagic endometritis with polyp, chronic perimetritis and salpingitis, diploe marked, atrophy of brain, especially frontal, pre- and postcentral and angular gyri, excess cerebrospinal fluid, basal arteries sclerosed, left ear drum ruptured, cord soft.

The most striking lesions accompanying the dysentery are the abscesses of the lungs, the infarct of the spleen, thrombus of the iliac artery and the acute hemorrhagic endometritis. From the fundus and cervix the third organism was present in abundance of colonies and is identical with the "organism to be especially studied," isolated from the blood and mesenteric lymph node in the case of "ulcerative vaginitis complicating a case of dysentery" (Epidemic, 1908), i.e., a Gram-negative bacillus, which does not produce gas, peptonizes milk, produces indol, is motile, liquefies getation and has a bleaching and coagulating action on the litmus sugar-serum-water of Hiss; is not agglutinated by antidysenteric serum.

The relation of this bacillus to hemorrhages, small and great, seems more than a coincidence, since it has been recovered from hemorrhagic cystitis, submucous hemorrhages in gastric and vaginal walls, in bloody mucus in the intestinal tract, etc.

No cultures were taken from the heart's blood, but from the cerebrospinal fluid and a mesenteric lymph node a coccus was recovered. Serum saved from the pericardial sac at autopsy failed to agglutinate the stains of B. dysenteriæ above mentioned.

XIII.

Primary Adrenal Tuberculosis in Juvenile General Paresis with Meningeal Infection (Bacillus Coli Communis).

BY E. T. F. RICHARDS, M.D., C.M.,

Assistant in Neuropathology, Harvard Medical School; Assistant Physician, State Infirmary, Tewksbury, Mass.; formerly Research Student under the Proctor Foundation at the Danvers State Hospital; Hathorne, Mass.

(From the Laboratory of the Danvers State Hospital, Hathorne, Mass.)

INTRODUCTION.

The following case presents so many features of interest that it has seemed worthy of being placed permanently on record.

Tuberculosis of the adrenal glands is a rare

pathological finding even in autopsies showing advanced tuberculosis of other organs. Its occurrence primarily and solely in the adrenals is limited to only a few authentic cases. In the present instance it will be noted that both glands were extensively diseased, but minute search failed to reveal any evidences of tuberculosis elsewhere.

Considered clinically, many of the classical features described by Addison were present, viz., marked asthenia and apathy; severe and frequent gastro-intestinal symptoms (the disease probably commencing with the attack of so-called "acute indigestion" six years prior to patient's death); attacks of extreme cardiac weakness with the characteristic small, low-pressure pulse. On the other hand, pigmentation of the skin (usually the most striking clinical feature) was limited to the external genitalia (these being colored a deep brown).

It is of interest that the thymus gland was present and fully developed, as its persistence has already been observed in a few cases of Addison's disease. That it plays any part in the symptomatology of the condition is a matter of doubt.

Viewed from the neurological aspect, we have a well-marked train of clinical symptoms confirmed by findings at autopsy, pointing to the diagnosis of dementia paralytica, occurring in a youth and in one in whom no history of syphilis or likely possible opportunity for infection existed. Many puzzling features of the clinical course (at variance with the ordinary symptoms of general paresis) are at once made clear by the findings at autopsy of the remarkable combination of advanced adrenal disease and well-marked chronic meningoencephalitis.

Bacteriologically, the cultivation of bacillus coli communis from the cerebrospinal fluid and from the mesenteric lymph nodes is in accord with findings previously reported from this laboratory, and suggests a probable mode of entrance of many of the late (frequently slight and often apparently unimportant) meningeal infections brought to light in the course of routine autopsy bacteriology.

The details of the case are as follows:

CLINICAL SUMMARY.

Patient is a white male, aged twenty-three years; is quite unable to give any facts relative to his illness, and the following information is furnished by his parents:

After an apparently normal early childhood, he began at the age of eleven to experience difficulty in carrying out his every day school tasks. From then on his mental capacity slowly but progressively deteriorated. Not only in his school work was this deficiency evident, but, in addition, he became dishonest and untrustworthy and developed untidy, uncleanly habits. "At the age of sixteen," his parents state, "he acted and behaved as a child of six."

In his seventeenth year he was taken with a severe attack of so-called "acute indigestion." This seemed to be the starting point of a generalized gradual paresis, as from then on, it is stated, he began to slowly lose the use of his limbs. By the time he had attained the age of twenty-one his writing had become illegible and his limbs so weak that he was unable to get into or out of a carriage. In his twenty-second year he was committed to the Danvers State Hospital.

Notes on admission indicate that the patient appeared from eight to ten years younger than the age given (twenty-two). Subcutaneous fat excessive, muscular development fair. Marked tremor of the extremities and tongue, accentuated by voluntary movements. The left eye diverged outward, and the left pupil was smaller than the right. The skin of the genitalia and groins showed an excess of pigment, but the axillæ, areolæ of nipples and mucous mumbrane of mouth were free. Genitalia undeveloped. No palpably enlarged glands. *Heart, lungs* and *abdomen* negative. Temperature, pulse and respiration normal. The neurological data contained much of interest. There was a generalized muscular weakness, but no actual paralysis. The patient was unable to walk in a straight line, and Romberg's position could not be maintained. Marked tremor was present in the hands and lips. There was bilateral impairment of vision and nystagmus. Reflexes and sensations normal. Speech was markedly affected, all syllables being very much slurred. School knowledge and memory for both recent and remote events very poor. The patient's habits were very untidy. He was very emotional, easily made to laugh or cry; and in behavior, extremely childish.

Two months after his admission to hospital, the weakness suddenly became extreme. He was constantly nauseated, refusing food. The face and hands were cyanosed and the heart's action rapid, weak and irregular. This attack lasted for a week and was followed by a period of improvement, during which, however, he still remained very weak and apathetic.

One month later he again became so feeble that he was unable to raise himself in bed. He complained persistently of feeling very "sick." His temperature was elevated and there occurred the same train of circulatory symptoms observed previously, viz., rapid and tumultuous action of the heart, with cyanosis of face and extremeties. He soon became unconscious, remaining so until his death, which occurred on the seventh day of the acute attack.

Autopsy Report. Head, E. E. Southard; trunk, E. T. F. Richards; cord, M. M. Canavan.

Body of an extremely well-nourished white male, aged twenty-three years. Absence of hair on face and in axillæ. Pubic hair abundant. Body length, 143 cm. Rigor mortis present. Marked lividity of dependent parts. Pupils slightly irregular in outline and slightly unequal in size; right, 6 mm.; left, 5 mm. Over the lower end of right radius, 2 cm. above tip of styloid process, is an old irregular scar firmly binding skin to subjacent bone. On inner aspect of lower third of right leg the epidermis is raised by a collection of clear serum for about a distance of 3 cm. A similar

serous collection is present over the external malleolus of left leg. The skin of the genitalia and groins is of a dark brown color. No abnormal pigmentation of remainder of skin surface is to be made out.

Peritoneal cavity: Fat in abdominal wall 5 cm. deep. No free fluid. Omentum excessively fatty. Appendix retrocecal, 10 cm. long. Mesenteric lymph nodes not enlarged.

Pericardeal cavity: Normal.

Pleural cavities: Firm adhesions bind lower half of left lung to chest wall.

Heart: Weight, 260 gm. All valves healthy. Myocardium somewhat pale, but of normal consistency. Coronary arteries normal.

Measurements: Left ventricle, 1.5; right ventricle, 0.2; mitral valve, 9.5; triscupid valve, 11; aortic valve, 6.5; pulmonic valve, 7.5.

Lungs: Weight: Left, 320 gm.; right, 375 gm. Right lung is perfectly divided into four distinct lobes; upper and lower, and two central or middle lobes.

The posterior portions of the lower lobes of both lungs are very dark, and on section moist and frothy. Both lungs are crepitant throughout. Apices negative.

Liver: Weight, 1345 gm. Edge sharp. Cut surface somewhat greasy and pale. Substance of normal consistency.

Spleen: Weight, 120 gm. Not remarkable.

Kidneys: Weight, 290 gm. In both, capsule strips readily, leaving a smooth surface. Cortex, 5 to 8 mm. Glomeruli visible but not prominent. Cut surface somewhat pale.

Adrenals: Both are enlarged to about twice their normal size and are extremely firm. On section the ordinary dark soft tissue of the medullæ is completely replaced by numerous firm yellowish areas. These are in the form of circumscribed nodules, of uniform consistency throughout (nowhere showing any breaking down) and of similar appearance and distribution in both organs. The cortices appear normal.

Gastro-intestinal tract: Rugæ of stomach present but poorly marked. Intestines negative.

Bladder: Negative.

Testicles: Not remarkable.

Organs of the neck: Lying in front of and upon the arch of the aorta and the great vessels is a gland-like structure which, when traced upward, is seen to divide into two distinct lobes. These extend, one on each side of the trachea, up to the lower border of the thyroid, where they terminate. The structure from above down measures 7 cm.; laterally, 5 cm.; and in depth, 0.5 cm. Its cut surface is pinkish in appearance.

The *thyroid gland* is smaller than usual, measuring from left to right 5 cm.; while each lobe from above down is 2.5 cm.

Trachea: Mucosa thickened and reddened.

Head: Hair abundant, dark. Scalp normal. Calvarium, weight 435 gm., transparent in bregmatic region only, elsewhere thick and dense. The average thickness of the vertical plate of the frontal bone is 7 mm. The frontal bone shows a moderate thickening and hardening of the inner table with obliteration of diploe. Dura mater moderately adherent to bregmatic region of calvarium. Arachnoidal villi moderately developed. Sinuses not remarkable. Pia mater shows a moderate focal thickening with opacity, especially along sulci. Vessels well injected. *Brain:* Weight, 1,200 gm. The brain shows marked focal variations in sulcation and consistence. Spread on a board, the right hemisphere is obviously somewhat bigger than the left. There is a difference of only 0.5 to 0.75 cm. on measurement of the greatest circumference of the cerebrum, taken from the median line superiorly to the median line inferiorly, but the right hemisphere is throughout slightly more convex than the left. Both *postcentral* gyri are much narrowed in their superior portions, and the sulci posterior thereto are deeper than the other sulci of the hemispheres. The sulci of the orbital surfaces are asymmetrical and, on the left side, show a tendency to microgyria. The cerebral hemispheres as a whole show a remarkable tendency to slight protrusion of the border gyri; thus the gyri of the two poles, of the free edges along the great fissure, and most strikingly the gyri at the boundary line between the inferior and lateral surfaces. This *marginal prominence* is slight but obvious and is emphasized by a slightly paler color in some regions. The cerebrum shows a general induration which is greatest in the frontal tips and along the inferior borders of the lateral surfaces of the hemispheres, especially right. The orbital surfaces are firm, especially anteriorly and externally (prefrontal); the tips of the temporal lobes are firm, and the superior temporal gyri are firmer than adjacent gyri. The postcentral gyri are indurated more than the other gyri of the superior surface. The hippocampal gyri are likewise firmer than adjacent gyri.

Cerebellum and pons: Weight, 145 gm. The inequality of the two hemispheres is more marked than in the case of the cerebrum.

Greatest lateral diameter; Left, 4.5 cm.; right, 5.5 cm.

Anteroposterior diameter adjacent to notch: Left, 5.8 cm.; right, 5.5 cm.

There is no appreciable difference in depth. The diminution in volume appears to be chiefly at the expense of the *right clivus*. The inferior surface is firmer than the superior. The laminæ adjacent to the horizontal fissure are firmer than the remainder of the cerebellum. The *pons* is small.

Middle ears not remarkable.

Retinæ show no gross lesions.

Spine: There is a sharp right lateral curvature in the lower cervical region. The bony canal is narrowed in its entire length. Dura adherent to pia-arachnoid. Cervical portion of cord much softer than normal.

Anatomical diagnoses: Bilateral adrenal tuberculosis, persistent thymus, hypostatic congestion of lungs, tracheitis, chronic adhesive pleuritis, four lobes in right lung, chronic gastritis, obesity, small thyroid, irregular and unequal pupils, pigmentation of genitalia and groins, dense calvarium, chronic osteitis (frontal bone), chronic external adhesive pachymeningitis, chronic sulcal leptomeningitis, right hemisphere larger than left, atrophy of superior portions of postcentral gyri, asymmetry of orbital gyri, microgyri (orbital) of left side. Marginal prominence of cerebral gyri with gliosis, general cerebral gliosis, especially frontal, temporal, orbital, postcentral and hippocampal gyri, atrophy of right clivus, gliosis of inferior cerebellar surface, gliosis along horizontal fissure, pons small, lateral curvature of spinal column, adhesions between spinal dura and pia mater, cervical cord soft.

Autopsy bacteriology. — The bacillus coli communis was isolated in pure culture from the mesenteric lymph nodes and from the cerebrospinal fluid in cultures taken at the autopsy table. The heart's blood contained a Gram-positive, non gas-producing bacillus.

Guinea pigs inoculated intradurally with cultures of the colon bacillus obtained from the cerebrospinal fluid and subsequently killed, showed patchy meningeal exudates made up of lympho-

cytes with occasional polynuclear leucocytes and eosinophiles.

Microscopical examination. — Adrenals: The central portions are in their entire extent converted into a diffuse homogeneous material, which stains poorly. Beneath the capsule there is an extensive heaping up of lymphocytes with an occasional scattered polynuclear leucocyte. Only in one or two small isolated areas does the normal columnar grouping of cells remain. In many places along the edge of the homogeneous caseating center there are well-preserved giant cells. Toward the extremity of the organ there are several small areas which show necrosis and giant cells with surrounding lymphocytic infiltration and beyond this newly formed connective tissue. Scrapings from the cut surfaces of the glands contain many tubercle bacilli.

Lungs: Sections from the posterior portions show the alveoli filled with red blood cells in various stages of degeneration, scattered leucocytes and occasional epithelia cells. The capillaries are much congested and in many places broken through into the alveoli. Sections from the apices and elsewhere reveal only normal lung tissue.

Heart muscle: Normal.

Kidneys: Lining epithelium of the tubules well preserved. Glomeruli not unduly congested. No connective tissue overgrowth.

Thymus gland: Cellular elements for the most part collected into compact areas of considerable size, the intervening substance being made up of fat and connective tissue. Hassall's corpuscles numerous and well preserved.

Pancreas: Negative.

Spleen: Negative.

Thyroid gland: Not remarkable.

Lymph nodes: Not remarkable.

Cerebral cortex: The diagnosis can readily be made of general paresis in the sense of a chronic meningo-encephalitis showing lymphocyte and plasma-cell infiltration of the vessel walls, irregular nerve cell destruction and corresponding gliosis. The picture in the frontal region is especially characteristic. The plexiform layer contains an excess of neuroglia cells.

XIV.

A Case of Autochthonous Sinus Thrombosis.

BY F. ROBERTSON SIMS, M.D.,

Assistant in Neuropathology at the Harvard University Medical School formerly Assistant Physician, Danvers State Hospital.

THE following is a study of a case of extensive sinus thrombosis of the cerebral sinuses. It is of interest because of the extent of the thrombus and the slowness of its development; also because of the probable origin in a focus of sclerotic vessels in one of the lateral sinuses.

The present history has been condensed from notes taken during the service of the writer at the Danvers State Hospital. The case was studied while on the wards of Dr. H. W. Mitchell.

Clinical history. — The patient was a merchant, forty-nine years of age. His family history was good. He had been a rugged healthy man, having had but one illness, an attack of tonsillitis six years previous, but during the last year he had suffered frequently from headaches, at times severe, though not so as to interfere with his business. He smoked excessively, but did not use alcohol. Syphilis and gonorrhea were denied.

On April 1, 1905, after attempting to suppress a sneeze, he complained of a sensation of something having given way in the left side of his head. A few minutes later a very severe headache developed. This headache was chiefly on the left side of the head and was accompanied shortly by nausea and excessive vomiting. Vomiting, pain in the head and epigastrium, persisted for twelve hours before any relief was obtained.

The second day he appeared dazed and confused, his speech was thick and difficult to understand, probably at times incoherent and periods of semi-consciousness developed when he could scarcely be aroused. There was very little change in this condition for four weeks. His temperature during this time varied from 97° to 99°.

In the fifth week a gradual change developed. He grew emotional, frequently crying when he attempted to speak with friends. He was also very restless and irritable. Visual hallucinations became prominent and in reaction to these he made vicious attacks on his nurses. It became difficult to restrain him and he was committed to the Danvers Insane Hospital on May 6.

When admitted he was in a stuporous state, lying with eyes closed, quiet or mumbling to himself and could not be aroused to answer questions with intelligence.

Physical examination. — Patient was a man of large frame, exceptionally well developed and nourished. The lungs showed moderate dulness and a few râles at both bases. The heart sounds were faint. The radial and temporal arteries were soft. The pulse was regular but showed very poor tension; rate, 96. The tongue was dry and heavily coated. The urine was concentrated, showing a trace of albumin, but no renal elements were found.

Neurological examination. — The patient had little general muscular strength and all movements were feeble and uncertain. There were no paralyses, but weakness was more evident on the right side. The cranial nerves in general, as far as could be tested with patient's lack of co-operation, were unaffected. The tongue protruded in the median line, but was turned to the left with difficulty. There was no marked difference in the labio-nasal folds.

Reflexes. — Knee jerks, right very lively; left, sluggish. The Achilles tendon reflexes were obtained on both sides. Ankle clonus and Babinsky reflex were absent. The right elbow jerk was more lively than the left. The pupils were equal and regular and reacted promptly to light and accommodation.

Sensations. — The right leg and foot were much cooler to the touch than the left. Reaction to pin pricks appeared equal on both sides and response was fairly prompt and active. Temperature, variable, 98° to 100.8°.

Note. May 9, 1905. The condition of the patient has been variable; for the most part he has been restless and active, pulling at the bedclothes and attempting to climb out of bed. He occasionally calls out for somebody in a loud voice. In reaction to an hallucination he made an attack on an attendant, accusing him of killing some one. He became quiet with small doses of veronal. At intervals he makes intelligent response to questions, showing a fair orientation for time,

but is confused for place and persons. His speech is very difficult to understand, remaining thick and paraphasic. Tests show both motor and sensory aphasia and a disturbance of the stereognostic sense, objects being fairly well recognized in the right hand, but not in the left. Hallucinations are constant, particularly visual. Pulls and searches the bedclothes, makes diving and dodging motions and sees relations sitting beside him. On being examined by physician he showed partial insight into his condition and made some attempt to follow out directions. Cries frequently when mention is made of his condition and also without any apparent cause. Occasionally flinches and cries out as if in pain when being moved, though no tenderness can be elicited. Takes nourishment only upon urging. Temperature not above 99.2°. Blood examination shows hemoglobin 95%, red count 6,400,000, white count 8,000.

May 13. Much weaker and less restless. Lies in a stupor most of the time, with head and eyes turned to the right. Pupils are small. Reflexes are lively throughout, right side possibly more so than left. The left arm is apparently spastic on motion. No Babinsky reflex or ankle clonus are present. When disturbed he cries out and becomes quite resistive.

May 17. Breathing has become stertorous and it has become difficult to arouse him from stupor. He rarely moves his extremities. The right arm and leg are flaccid on passive motion. Yesterday a Babinsky reflex was obtained on the right, otherwise there is no change in reflexes. Fundus examination shows marked injection of vessels, but was otherwise negative. A cough has developed and symptoms of bronchopneumonia. Temperature varies from 99.4° to 101°. Coma became deeper and he died on the afternoon of this date.

Clinical summary. — A rugged, healthy man of forty-nine, with history of frequent severe headaches for a year, has an attack of sudden onset, with violent headache and vomiting lasting over twelve hours. Periods of somnolence, aphasia and increasing weakness of the right side follow, with temperature chiefly subnormal. Later hallucinations, delirium, hemiplegia, deepening stupor and coma, death at the end of six weeks.

Autopsy eight hours post-mortem by Dr. A. M. Barrett showed an acute purulent bronchitis and pulmonary hypostasis with areas of consolidation. Cultures from the heart's blood and spleen were negative, but from the liver the streptococcus pyogenes and a colon-like bacillus were obtained.

The brain weighed 1460 gm. The diploe in the lateral parts of the calvarium were moderately congested. The dura was lightly adherent over the frontal region. The left sigmoid and transverse sinus was filled with a mixed red and gray clot, apparently filling the entire lumen and intimately adherent to the dura. This continued into the longitudinal sinus, but here the clot was narrower, only partially filling the lumen; it was more reddish than gray and less adherent than lower down. Save for slight congestion of the cancellous tissue, the temporal bone was not notable. The pia mater was clear except for a few small hazy flakes along the course of the larger vessels. The vessels of the pia were moderately congested. The basal arteries were free from gross changes. The brain was of good consistency. The ependyma of the fourth ventricle was finely uneven. Save for a general pinkish coloration of the cortex and slight congestion of the vessels of the white substance, the brain was not notable.

Microscopical examination. Sections from the thrombus show a fairly well-organized blood clot, with numerous new formed blood vessels and many phagocytes filled with coarse brownish-yellow granules. Areas of fresh hemorrhage appear in the sinus wall as well as in the thrombus. Leucocytes do not appear in any numbers. In the sinus wall are a few small arteries with quite marked arteriosclerotic changes, some of which show a proliferation of the endothelium almost obliterating the lumen.

Cortex (superior, frontal, precentral, temporal, calcarine, regions studied, E. E. 8.). — The blood vessels of the cortex are dilated and much congested everywhere. No marked sclerotic changes are observed either in the larger arteries of the white matter or the small cortical vessels.

Study of the neuroglia and nerve cells show chronic and acute changes. There is a mild degree of cellular gliosis of the white matter, also a mild fibrillary gliosis forming the extreme outer shell of the subpial layer (Heidenhain stain). Of the more acute changes, the best examples are found in the layer of large external pyramidal cells and in the substellate layer were numerous cells more or less replaced by satellites. This later change seems to be focally more severe.

Nissl preparations demonstrate cell bodies of a spongy yellowish appearance due to a form of pigment scattered diffusely through the cell body. This pigment was especially studied in Heidenhain preparations, which demonstrate varying degrees of change. This pigment appears in varying amounts in and around many of the blood vessels. The same regions which exhibit the most marked satellitosis tend to show in Heidenhain preparations the most marked intracellular pigmentation, i.e., the layer of large external pyramids and the substellate region.

The nuclei are only occasionally destroyed. Very few definite examples of axonal reaction are shown. For example, in the motor area the large motor cells show great variation in staining quality, size, appearance of nuclei and Nissl bodies, but axonal reactions are almost never in evidence.

Anatomical summary. — Bronchopneumonia, a well-organized thrombus filling the left sigmoid and transverse sinus and extending into the longitudinal sinus. Moderate congestion of the vessels of the cerebrum. Focal sclerotic changes occurring in the walls of the affected sinus.

Chronic cellular and fibrillary gliosis in the cortex, chronic perivascular cell pigmentation, acute changes in the nerve cells with general intracellular pigmentation and satellitosis. The layer of large external pyramids and the substellate regions in general exhibit the most severe changes.

Discussion. — The case was clinically doubtful. The most likely diagnoses made in life were brain tumor, apoplexy and meningitis. Upon review of the complete history, it seems that brain abscess, encephalitis and sinus thrombosis might well be considered in similar cases. The true diagnosis of sinus thrombosis was not seriously thought of by any of the physicians dealing with the case in life.

Considering these possible diagnoses more fully, we had in favor of brain tumor the subacute course with stupor, gradually developing weakness and aphasia. On the other hand, the sudden onset with headache and vomiting more severe at first, while later disappearing; and also the absence of optic neuritis were strongly against this disease. The same considerations applied largely to brain abscess. The majority of cases of brain abscess occur by extension from some purulent or destruc-

tive process, most commonly otitic in origin. No primary focus of infection was evident in the examination of this case. The character of the pulse might have helped in deciding against brain abscess. As in the latter condition, the pulse is generally slow. This case had rapid pulse.

Encephalitis may run a very similar course, particularly the acute hemorrhagic encephalitis (Strümpell type). An acute onset without prodromal symptoms is the rule, though generally the course is short, fulminating and characterized by high temperature. Also this condition is rare in adults.

The evidence for meningitis was slight in the absence of the common phenomena of muscular rigidity and contractures. Also important was the absence of pyrexia until late in the course of this disease (explainable by pulmonary complication).

Apoplexy was not likely with the history of this case unless one considered the onset of severe headache and vomiting in the light of prodromal symptoms, followed later by periods of semiconsciousness due to hemorrhage. The aphasia and hemiparesis, as well as the mental disturbance, were consistent with such a diagnosis. But strongly against the diagnosis of apoplexy was the markedly low tension pulse.

In this case the symptom most characteristic of sinus thrombosis was missing, i.e., congestion of the veins of the cranium and face. Oppenheim states that, in the absence of this symptom, no positive diagnosis can be made.

Bertier distinguishes between surgical thrombosis, which is usually due to some local cause, suppurative in nature and limited in extent, and medical thrombosis, which arises from general blood states or causes acting from a distance and which is non-suppurative and widespread in character. He says in adults chlorosis acts as the most important predisposing factor for medical thrombosis. Many authorities agree that a lesion of the endothelial lining of a vein is essential to the formation of a thrombus. In most cases this is undoubtedly of organismal origin, but one cannot affirm that all are due to an infective agent. In this case no focus of infection was found and the microscopic appearance of the thrombus does not favor it.

Talley and Wimmer each report very similar cases. Talley's case was of a woman of forty-six who had constant headaches for two years. Headaches became rapidly worse and were accompanied by nausea and vomiting. There was extreme distention of the veins of the head and neck. The arteries were hard, pulse was slow, 40–60. Her temperature varied between 96° and 99° throughout. The persistent headache gave way only to begin coma. Death occurred three weeks after the acute onset. An extensive partially organized sinus thrombus was found at autopsy. No seat of infection was discovered.

Wimmer's case was a man of fifty-two, suddenly seized at work with paralysis of the right arm and general trembling, followed by weakness in the right leg and the same evening twitching in the right side of the face. There was no loss of consciousness during the first day. Convulsive attacks beginning in the right arm, followed by a condition of coma, lasting half an hour, developed and recurred at frequent intervals, death in four days. There was found thrombosis of all the large sinuses, of the minute pial veins and small hemorrhages. The cortical arteries were unaffected.

Sinus thrombosis in adults is productive of quite complex symptoms. According to Bertier, violent headache, followed at varying intervals by cerebral vomiting, vertigo, epileptic seizures, paralyses, delirium and coma, would constitue a typical case resulting from severe chlorosis. Hyperpyrexia may occur two or three days before the disease is fatal. Organization of the clot, with consequent hydrocephalus or paralyses, may occur. It is certain from a study of this case that absorption of the thrombus with complete recovery may occasionally take place.

The arteriosclerotic vessels in the sinus wall suggests a probable cause. A weak vessel gave way under the increased blood pressure and a small hemorrhage occurred. This led to other hemorrhages, starting a vicious circle similar to the condition found in internal hemorrhagic pachymeningitis. The fresh hemorrhages in the thrombus help to confirm this idea.

XV.

The Diagnosis of Fractured Skull Aided by the Finding of Brain Tissue in the Vomitus.

BY GORDON T. BROWN, M.D.,

Formerly Assistant Physician at Danvers State Hospital.

The following case illustrates a curiosity in the diagnosis of skull fracture, based on the finding of brain material in the gastric contents.

An electric car conductor, thirty-five, sustained a fracture of the skull from collision with a telegraph-post while on the running-board of his car. On removal to the Lawrence General Hospital, two hours after the accident, the patient showed an obvious depressed fracture of the right frontal bone, and while on the accident table began to vomit bloody fluid. The vomiting was extensive (1 to 6 oz.) and lasted eight hours. At the third or fourth attack of vomiting, a bit of material was observed on the blanket which macroscopically suggested fresh brain tissue. This suggestion was later microscopically confirmed. The patient died sixty-five hours after the accident. The patient spoke no words while in the hospital, but was restless, spontaneously arising from bed, was without paralysis and

would resist attempts at examination (such as gagging of mouth or lifting of eyelids) by inco-ordinate movements of arms and legs. On gagging the patient uttered long, loud, ah sounds. Later the patient groaned, habitually breathed through the mouth and a few hours before death became cyanotic.

The temperature in axilla, 101.2° nine hours after accident, rose to 102° eight hours later. Operation (removal of a fragment of the frontal bone by Dr. Durant, of Haverhill) was followed by temperature of 100° next morning. The temperature then rose steadily to 102.6° before death.

There was no systematic examination of reflexes. The knee-jerks were neither markedly decreased nor increased. The pupils were moderately and equally dilated.

The details follow:

Personal history: H. L. W., aged thirty-five, married. Conductor on the Boston & Northern Street Railway.

Accident: On June 8, 1907, 11 P.M., patient stepped from the rear platform onto the running-board of the car, which was going very fast and around a curve, where fares are not generally collected on account of closeness of the car to the trees and posts. He was immediately struck on the head by a telegraph-post which was leaning toward the track. Patient was knocked off the car and taken to a drug store and thence to the Lawrence General Hospital, where he arrived at about 1 A.M. June 9, 1907.

Examination: In the admitting room patient remained quietly in a dorsal decubitus. Pulse 88, good volume and tension, slightly irregular. Respirations, 40. Eyelids greatly swollen and closed and were with difficulty opened. Pupils moderately and equally dilated and did not react to light. Over the left frontal bone there was seen a deformity, apparently that of a depressed fracture. Palpation confirmed this view. Patient began to vomit blood and stomach contents, the greater part of which were received in a basin. Once, however, the patient vomited so suddenly that some of the vomitus went onto the blanket on the table on which patient lay, and it was in this specimen of vomitus that a bit of tissue was seen, about 1.5 cm. by 0.5 cm. in size. On first inspection this looked like brain tissue. A section was made and this idea still further strengthened by seeing what was taken to be white and gray matter. Specimen was placed in alcohol. A mouth gag was then inserted which was very actively resisted by the patient, who yelled loudly. Blood was seen oozing from the nasopharynx, and this was spattered over physician by patient's screaming. Palpation of the pharynx and nasopharynx was tried, but examination was unsuccessful.

Subsequent history: Patient was then sent to the ward and continued to vomit bloody fluid for the next eight hours; he grew very restless and noisy and had to be held in bed. At 8 A.M., June 9, 1907, pulse was 72, respiration 32, temperature 100.2° by axilla. Patient was less restless at this hour, 8 A.M., unable to take nourishment and voided urine involuntarily. At 2 P.M., June 9, 1907, patient tossed his head about, groaned considerably. At 4 P.M., pulse 82; respiration 34; temperature, 102° F. and quite restless. At 6.30 P.M., pulse 110; respiration, 34. At 9 P.M., June 9, 1907, ether was given and patient operated on. An ugly depressed fracture of the right frontal bone was found, from which lines of fracture ran in different directions, one downwards towards the anterior fossa; the right frontal bone was quite movable. A piece of bone 3 cm. by 2 cm. was removed and patient sent back to ward at 10.15 P.M. Pulse, 90; respiration, 26. At 11.45 P.M., June 9, 1907, respirations were slightly irregular and patient again became quite restless and had to be held. Voided at this hour involuntarily. At 4 A.M., June 10, 1907, pulse, 72; respiration 30; patient still restless. At 8 A.M., same date, pulse became irregular and varied from 80 to 120; temperature 100° F.; respiration, 30. At this hour he took ounces of liquid nourishment with difficulty, which he continued to take every three hours until 12, noon. June 11, 1907, with increasing difficulty. June 10, 1907, 4 P.M., pulse, 110; respiration, 38; temperature, 102.2°; both pulse and respirations irregular. At 8 P.M., same date, respirations became Cheyne-Stokes in type and patient had become quiet and remained so until death. June 11, 1907, 4 P.M., pulse 140, very irregular and weak; respiration, 72; expelling brown-colored froth with each expiration and patient cyanotic. June 11, 1907, 12 P.M., pulse, 140+, weak and irregular; respirations 70 and irregular; temperature, 102.6° F. June 12, 1907, 4 P.M., patient died.

Autopsy: A partial autopsy was performed by Dr. Dow, medical examiner. The diagnosis of skull fracture was confirmed. From notes of this autopsy it is gathered that there was an extensive stellate fracture of the right frontal bone. A small portion of bone was found loose in the extradural space at the locus of fracture; this piece had not been removed at operation. Beside this remaining fragment of bone, there was an extradural clot, presumably largely an effect of operation. After removal of the brain, a fracture of the right orbital plate was found, continuous with the edge of the pre-operative depressed fracture and the whole cribriform plate had been subject to a comminuted fracture, among the fragments of which the posterior portion of the orbital plate had been imbedded. The orbital and lateral surfaces of the frontal lobe were subject to extensive laceration. No accurate mapping of the dislocated areas was made. It seems likely that the posterior fragment of the orbital plate had been driven inward, slightly forward and upward, so as to override the anterior fragment. The possibility of this is indicated by the mobility of the broken frontal bone, when grasped by the free edge anterior to the depressed fracture, as demonstrated at operation. Such an injury might conceivably have clipped off a portion of the orbital cortex, which may then have been carried into the nose. It is unfortunately now impossible to localize or describe this mechanism more closely.

Microscopic examination. — Microscopic examination quite confirmed the anatomical diagnosis of brain tissue. Moreover, it seems possible to localize the original site of the vomited tissue as from some portion of cerebral substance having the intermediate precentral type of cell arrangement. And, if the surgical and autopsy data are also considered, it seems highly probable that the fragment was derived from that very small tongue of tissue having the intermediate precentral type which is prolonged from the flank of the hemisphere to the orbital surface. [1, 2]

The intermediate precentral cortex closely resembles the precentral or motor cortex proper in point both of fibers and of cells. The intermediate precentral cortex is somewhat less rich in nerve fibers than the precentral. The cell-picture in the outer five layers (plexiform, small pyramid, medium-sized pyramid, external large pyramid, stellate cell layers, according to the nomenclature adopted by Campbell) can scarcely be used in differentiating the two types, precentral and intermediate precentral. In fact, the most prominent differentiating feature is the absence of the large Betz or motor cells from the intermediate precentral area.

The area to which the vomited tissue probably belongs is accordingly of the general precentral or motor type and is distinguished, by its lack of Betz cells, as of intermediate precentral type.

On anatomical grounds one might assume a possible confusion with several other cerebral tissues, as olfactory bulb, frontal tissue, prefrontal tissue and perhaps temporal and hippocampal tissues. The olfactory bulb tissue and hypocampal tissue can be excluded by reason of very obvious absence in the specimen of the somewhat striking stratifications of those structures. The absence of a stellate layer of well-defined character in the specimen makes it difficult to conceive the tissue as of temporal origin and throws some doubt on the likelihood of frontal origin. The marked development of the internal layer of large pyramids in the specimen seems to eliminate the possibility of the prefrontal nature of the tissue.

Note Concerning Brain and Other Visceral Weights in Sixty-six Subjects Showing Carcinoma and Sarcoma.

NEWELL B. BURNS, M.D.,

(Laboratory Interne, Danvers State Hospital, Massachusetts, 1909.)

The general emaciation occurring in cases of carcinoma and sarcoma has suggested a comparison of the brain weights in such cases with existing data as to normal weights for corresponding ages, and also of certain visceral weights. Furthermore, experimentation has shown that the effects of starvation upon animals are such that the heart and brain suffer comparatively little tissue loss, whereas the kidney and liver are affected to a great degree.[1]

The object in view is to learn:

1. How much variation, if any, there is between the affected and normal brain weights.

2. How much variation, if any, there is between the affected and normal visceral weights.

3. The comparison of ratios of variation between (1) and (2). The data are taken from the autopsy records of the Danvers Insane Hospital, by permission of Dr. E. E. Southard; the Massachusetts General Hospital, by permission of Dr. James Homer Wright; and the Boston City Hospital, by permission of Dr. F. B. Mallory. All cases indexed under carcinoma and sarcoma were taken, without particular consideration for this first study as to the degree of emaciation, duration of disease or terminal infection. A number of cases were necessarily eliminated owing to lack of data.

The data used as standard denominators in computing the ratios are from Vierordt's Daten u. Tabellen, p. 40. The visceral weights are in most cases the combined weight of heart, liver and kidney. Wherever the tumor involved either primarily or secondarily, one of these organs the weight of the remaining two, or even one, is taken.

[1] American Text Book of Physiology, vol. i, p. 363, Voit's table.

As there is probably a certain amount of error in the determination of brain weights at autopsy, allowance for such is made as follows:

	Gm.
Scales error,	5
Cervical cord length error,	5
Pia mater tearing error,	5
Withdrawn for culture,	10
Total error in one direction,	25
Total error in both directions,	50

On the basis of 1358 gm. as a normal brain weight 50 gm. would cause a variation in ratio of 4%. Accordingly, ratios from 0.98 to 1.02 inclusive may be considered normal on the ground that they show no significant variation in brain or visceral weights from normal.

The ratio of the affected brain weight (*numerator*) to the normal brain weight (*denominator*) is the criterion which determines in which of the three groups that case should belong.

The three groups are:

1. Those cases with brains showing ratios of variation below 0.98. 2. Those cases with brains showing ratios of variation above 1.02. 3. Those cases with brains showing ratios of variation between 0.98 and 1.02 inclusive.

12 cases	12.01	11.85

SUMMARY.

Forty-six per cent. of the cases arrange themselves under Group I (underweight). Thirty-six per cent. of the cases arrange themselves under Group II (overweight). Eighteen per cent. of the cases arrange themselves under Group III (of approximately normal weight).

The fact that almost half these cases of malignant disease (carcinoma and sarcoma), drawn from general and insane hospital material, possessed underweight brains (98% or less of the normal assigned brain weights for their respective ages) leads to the question whether, after all, the nerve tissues may not lose weight much like other organs under certain circumstances.

Let us first see under what circumstances the brain weight is maintained at normal weight or even exceeds normal weight. There are 12 normal and 24 supernormal brain weights, i.e., 36 (or 54% in the series which may reasonably be supposed to have at least held their own with respect to weight. Obviously, if malignant disease is determining emaciation, it should, and frequently does exert an effect upon various trunk viscera by reducing their weights. Numerous examples of this effect are given in the above tables. If the brain were spared the weight-reducing process which malignant disease is known to exert, there should be numerous examples in Groups II and III of underweight trunk viscera alongside brains with maintained weight. Adopting the same normal standards for the trunk viscera as for the brain (0.98 to 1.02), we find in Group II but 6 cases in which the trunk viscera are differentially reduced (25% of the overweight brain series), and in Group III, 5 cases (42%). That is, only 11 cases in 36 show trunk-visceral weight-loss in the presence of maintained brain weight (30%). Moreover, removing 11 cases from Group II and 5 cases from Group III on the ground that weights from all three chosen trunk viscera were not used (being affected with tumors or otherwise not available), we find that Group II shows 4 cases and Group III only 1 case of trunk-visceral weight-loss with maintained brain-weight (25% of the series, now reduced to 20).

It must be conceded, however, that this argument looks both ways. We cannot consider every loss in brain weight as here due to malignant disease, if it turns out that the trunk viscera are meanwhile maintaining their weights. In Group I, in fact, we find 16 cases (or a little over half) which present this curious relation of maintained or excessive trivisceral weights in the presence of lowered brain weight.

We must recognize at once that there are many cases in which malignant disease, for one reason or other, fails to reduce the brain weight (54%).

In many cases, also, malignant disease fails to reduce the weight of the organs at large (62%), at least as indicated by our chosen viscera. Statistically, therefore, there seems at this point to be actually more likelihood of brain weight loss than of trunk-visceral weight-loss in malignant disease.

How far do the brain-weight loss and the trunk-visceral weight-loss coincide? Twenty-one per cent. of the total series show such general loss.

In case neither the brain nor the trunk viscera exhibit loss in weight, we may well suppose that the weight-reducing factors in malignant disease either did not exist in those particular instances or did not have time to operate. *Either* brain weight loss *or* trivisceral weight loss, *or* both, supervened in 71% of the series, or 47 cases. Adopting these 47 cases as the basis of calculation, we find:

Thirty cases show brain weight loss, 64%; 25 cases show "trivisceral" weight loss, 53%; 14

cases show brain and "trivisceral" weight loss, 30%. So far, then, as these data go, there is at least as much evidence for brain-weight-reducing factors as for (heart-liver-kidney)-weight-reducing factors in malignant disease, a result somewhat unexpected in view of current physiological views.

XVII.

Some Effects of Over-Feeding with Fats in Certain Cases of Insanity.

By Herman M. Adler.

It is a well-known fact that aged or insane persons generally have a lowered resistance to infection. This observation, which is a familiar one in all institutions for insanity, is supported by the findings at autopsy. In a large number of cases of insanity, the lymphatic system, lymph nodes, spleen and lymphoid tissue which are chiefly concerned in resisting the invading agent, show at autopsy a reaction to infection which is visibly less than occurs in the average individual. An investigation of this point which is being carried out at this laboratory has disclosed in numerous cases a morphological basis for this lowering in resistance, namely, an atrophic condition of the lymphoid tissue. This is particularly striking in the spleen which as a rule is reduced in size, the weight varying from 150 gm. to as low as 7 gm. The mesenteric lymph nodes as well as the lymphoid tissue of the intestine are involved in this general deterioration. This is demonstrated in part by the condition found in the gut and mesenteric lymph nodes, especially in the autopsies of cases of dysentery.

It has recently been pointed out [1] that the lymphoid apparatus is concerned not alone in the management of toxic agents that have passed the outer epithelial barriers of the body, but with the transport and disposition of the large class of fatty substances of which the toxins form only a group.

Stheeman concludes that the lymph glands are organs which prepare the fats derived both from the food and from the fat depots for the internal metabolism of the tissues.

Fat on entering the intestinal lumen is split up into fatty acid and glycerin. In the form of fatty acid combined with bases as soaps it is absorbed by the epithelium. It has repeatedly been shown that on emerging from the intestinal walls into the lacteals it is again in the form of neutral fat. Somewhere in its passage through the intestinal wall the fatty acid has been reunited to glycerin. It has not been shown where this change occurs, but it is assumed that the epithelium of the intestine is responsible for it. The glycerin is not necessarily derived from the original neutral fat, but may be supplied in the wall itself, as has been proved by the experiments of Munk.[2] Munk fed fasting dogs with fatty acids and observed that no fatty acid appeared in the lacteals, so that the glycerin which converted the fatty acid to neutral fat could not have arisen from the food. Faust and Tallquist [3] have pointed out this fact in connection with their experiments on pernicious anemia due to Bothriocephalus toxin. This toxin they proved to be oleic acid, which is capable of producing intense hemolysis, while the fatty acids of the other two most common fats, stearic and palmitic acids, do not produce any hemolysis. Since, then, the hemolytic agent in Bothriocephalus anemia is oleic acid, and since the ordinary food fats taken in considerable quantities at each meal are split up by the digestive ferments into fatty acids of which a large part is oleic acid, the question arises why any one should be able to resist the oleic acid hemolysis. Faust and Tallquist are forced to the assumption that possibly a factor in the Bothriocephalus anemia is the inability of the intestinal wall to supply glycerin. By feeding very large doses of oleic acid to dogs, Faust has been able to induce a certain degree of anemia, by no means, however, comparable to the pernicious type. I have myself become convinced, after long-continued subcutaneous injection of oleic acid into rabbits, that only a slight anemia can be produced in this way. The slight degree of anemia is quite out of proportion to the intensity of the reaction when red blood corpuscles are brought into contact with oleic acid in the test tube.

In view of these facts, the idea suggested itself that possibly the condition of the intestinal lymphoid tissue might be responsible for the extent to which the fatty acids were converted into neutral fats. Judging by the autopsy protocols, it seemed not unlikely that certain cases of insanity that gave evidence of lymphoid atrophy should react differently to the introduction of fats, in larger quantites, than the normal healthy person. Since the lymphoid tissues are not comprised in one organ, but are diffusely placed all through the body, it is not a certain or an easy matter to determine its condition in a given individual. It was decided, for want of a better index, and in spite of several objections that might be raised, to be guided by the size of the spleen. A number of patients were examined, but finally only a few, namely, those in whom it was impossible to detect the presence of the spleen, either by percussion or by palpation, were selected. The sera of these cases were then examined for hemolytic properties. None showed hemolytic properties either to their own corpuscles or to those of other individuals. The patients were then given a diet consisting only of milk, and serum was obtained at intervals of a half hour during digestion. In a number of cases autohemolysis was observed, which continued during the period of milk diet. The amount of milk given varied. In a few of the patients, autohemolysis appeared after two or three glasses of milk had been given. In others the milk feeding had to be continued for twenty-four hours and the quantity increased to several quarts a day before autohemolysis appeared. In all these

[3] Faust and Tallquist: Arch. für exp. Path. und Pharm., 1908.

cases autohemolysis disappeared on the withdrawal of milk and butter from the food, to reappear again on the renewal of a fat diet. In the remainder of the cases observed in this connection, no autohemolysis could be detected even after large meals of milk and butter.

The cases which showed the autohemolytic reaction after fat feeding were all more or less emaciated and slightly anemic. The blood examination in no case showed a severe degree of anemia. The hemoglobin was never below 80 by the Tallquist scale. The red count was four million or over. No nucleated red cells or poikilocytosis were observed. Leucocytes were not increased, and no abnormal forms were seen. While these observations are relatively few, and much is left for further study, it appears on account of the very definite nature of the reaction when it occurs that a consideration of the possibilities involved may not be out of place.

tissue, a large number of cases picked at random, including some of the laboratory staff, were examined under ordinary dietary conditions, and after taking a large amount of fats. In no case was the serum hemolytic.

While chance is not entirely ruled out by the small number of positive observations, the regularity of the occurrence of hemolysis after fat feeding, and its absence after fat-free diet, makes the relation of the one to the other highly probable. Another factor that is of importance in obtaining a positive reaction is the time after a meal that the blood is obtained. The specimen must be obtained during digestion, that is, while the fat is present in the circulation.

Suggestive as these results are, it is the large number of negative results in patients presenting outwardly no differences from the positive cases that attract attention. Evidently the body possesses means of defense against the introduction

			Normal serum + normal corpuscles	0

The accompanying extracts from the protocols show the results in three cases in which a positive hemolytic reaction was obtained.[4] Out of ten selected cases examined, 4 showed hemolytic properties. In these 4 the serum lost its hemolyzing properties during a period of fat-free diet, to regain it after the patient was again on a generous fat diet. As the total number of cases in which the spleen could not be located by physical examination was small, and as it seemed possible that this reaction need not necessarily be associated with a small spleen, or even have any relation to the lymphoid

of free fatty acid aside from its power of forming neutral fats from them. In order to investigate this point, the following experiment was performed.

One grain of sodium oleate was dissolved in 100 ccm. of 0.9% NaCl solution and the same quantity of sodium oleate was dissolved in 100 ccm. of a solution of salts resembling the constitution and concentration of the blood.[5]

This solution contains, besides Na, also K, Ca and Na in combination with HCl, H_3PO_4 and H_2CO_3 in an equilibrium identical with that of serum.

[4] The writer is indebted to Dr. A. M. Burgess, laboratory interne 1910, for aid in these determinations.

[5] Adler, H. M.: Experiments toward a Physiologically Isotonic Solution of Salts. Jour. Am. Med. Asso., vol. li, 1908.

These two solutions, containing sodium oleate in equal strength, were tested as regards their hemolytic properties. It was found that the sodium chloride solution was intensely hemolytic, while the second solution showed no hemolytic properties in any proportions, even after twenty-four hours in the thermostat. The explanation of this phenomenon is to be found in the fact that the calcium and magnesium soaps of oleic acid are insoluble in water, while the sodium and potassium soaps are readily soluble. When the sodium oleate was dissolved in the second of these solutions it was precipitated as calcium and magnesium soaps. The precipitate rises to the surface and is quite apparent to the eye. The experiment was next repeated, using oleic acid instead of the sodium oleates. After shaking the solution for fifteen minutes, no oil was to be observed floating on the surface, but the soaps formed had been partially dissolved. A test set up at this time showed hemolysis. After standing an hour in the thermostat, a layer of soap was seen floating on the surface of the solution, and a test showed no hemolytic property. Clearly, then, one of the things that may occur if free fatty acid is introduced into the body fluids, is the binding of calcium and magnesium and the withdrawal of these bases from the circulation. Calcium and magnesium may be considered thus as secondary defenses of the body in resisting the effects of free fatty acid. The bearing of these considerations upon such conditions as anemia and fat metabolism in general, including that of the central nervous system, is evident.

SUMMARY.

1. The organism has provision normally for converting the fatty acid products of digestion into neutral fats.
2. This power may be diminished under certain circumstances.
3. In those cases in which fatty acid is not entirely converted into neutral fats, the toxic effects of the fatty acids are neutralized in other ways.
4. One of the methods by which free fatty acid is neutralized is by conversion into insoluble soap.
5. When this occurs, the body suffers a depletion in its calcium and magnesium content.

Book Reviews.

The Care of the Child. By Mrs. Burton Chance. Pp. 242. Philadelphia: The Penn Publishing Company. 1909.

This little book according to the preface "is not intended in any way to take the place of medical advice, nor does it presume to give suggestions upon any more vital questions than those pertaining to the practical care of the normal child. It is designed with the hope that it may help the average mother to solve her daily problems."

The first half of the book, which is devoted to the care and feeding of the baby and child, is about up to the average of such books and only reasonably satisfactory. The second half of the book, on the bringing up of children, is remarkably good. We would call attention especially to the emphasis laid on the importance of example, the necessity and the methods of developing obedience, the control of bad habits, the importance of sympathy, the recognition of the large part which imagination plays in childhood, and the importance of paying due regard to the rights of the child's personality. There is no mother, or father, either, for that matter, that will not be benefited by the careful perusal and consideration of the last four chapters.

An Index of Symptoms. With Diagnostic Methods. By Ralph Winnington Leftwich, M.D. Fourth edition. New York: William Wood & Co. 1910.

That this book should have reached a fourth edition is probable evidence that it has met a considerable demand among practitioners. It is intended less as a manual of diagnosis than as an index for reference, and contains a quantity of miscellaneous information marshalled under various captions into a fantastically ingenious congeries. Perhaps the most interesting part is the introduction, in which patients are classified as pessimistic, optimistic, complaisant, or mendacious, and in which the nine fallacies of diagnosis are stated and described as those of suggestion, antecedent disease, concurrent disease, obsession, perspective, variations within the normal, personal equation, transferred pain, and malingering. It is to be feared that diagnoses made solely in accordance with the methods of this volume would be subject to the still further fallacy of myopia.

The Diseases of the Thyroid Gland, Myxedema and Cretinism. By Dr. C. A. Ewald. Second edition, completely revised. Vienna and Leipzig: Alfred Hölder. 1909.

Since the appearance of the first edition of this work in 1895, great advances have been made in the knowledge of thyroid disease. The present volume, in classic form and with praiseworthy and characteristic German thoroughness, sums up and incorporates the details and results of this progress with the admirable original material. The book now includes careful consideration of thyroid anatomy and physiology, of acute thyroiditis, malignant struma, echinococcus, actinomycosis, syphilis and tuberculosis of the thyroid, goiter, cretinism, myxedema and cachexia strumipriva. Though sparsely illustrated, it deserves its position as a standard monograph on the subject. It contains also a valuable bibliography of recent literature on all affections of the thyroid gland, with the exception of Basedow's disease, which the author regards of such importance as to demand separate consideration.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, AUGUST 4, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

DEATH AN EXPENSIVE CUSTOM.

THE *American Magazine* for July of this year states that a committee appointed by the City Club of Chicago has been collecting facts in demonstration of the high cost of dying in that city. It is declared that undertakers are wont to take advantage of people who, in affliction, have neither time nor disposition for business considerations. As a result of a recent suit, an undertaker's bill was reduced from $552.50 to $302.50; and the defense for such extortion from a bereaved family was based upon the following reasons: The infrequency of funerals and the consequent period of idleness between cases; the large percentage of bad debts, coupled with the disadvantage that many such bills must go through probate; the ever-present danger of infection and of the loss of life in embalming. We shall not here dwell upon the puerility of such reasons, which are given as justifying the extortion of from 100 to 200% profit from human beings in the most melancholy circumstances they can experience. We do, however, emphasize (as our colleagues in hospital service have noted) the pathetic extravagence of the very poor in incurring funeral expenses in honor of their dead — how they spend money recklessly and without question for flowers, carriages and even bands of music.

But extortion from the survivors in a family does not seem to be confined entirely to these United States, if we may judge from the case of a Wisconsin gentleman who died recently of a heart lesion in a hotel near Naples. The landlord, it is reported, demanded from his widow 3,500 francs — 2,000 as damages because her husband had died in his hotel and 1,500 on account of the undertaker. The luggage of the most distressed and unfortunate lady was seized for the claim, and only after an appeal to the American consul was the matter settled by the payment of 500 francs, one seventh of the original claim.

Such extortion is, it seems, frequently attempted, especially in Southern Europe, on the ghoulish principle that the grief-stricken, in a strange land and under crushing stress of emotion, will let themselves be plundered without resistance. It is especially sought to victimize American travelers, on the often gratuitous assumption that they have more money than anybody else; perhaps, also, that they can be bullied with unusual ease.

Another case occurred several years ago in a small Italian town where an American gentleman, known to be very rich, died, also of a heart affection. The "*boniface*" demanded 25,000 francs for the "injury" done his hotel by the fact of the death having occurred there, besides 5,000 to "refurnish" the room the deceased had occupied; and the local physician, whose brother was the local apothecary, united in a claim for at least 2,000 francs more. Through the fortunate accident that an American who knew how to proceed in these premises, and how invoke the consular authorities in a way to be comprehended of the natives, was a resident of that place, the widow was saved more sorrow and trouble than she ever actually knew anything about and was enabled to take the body of her husband away upon the payment of something like a thousand dollars. In another case it is said to have cost the family of an American who died in Jerusaleum more than five thousand dollars to get him out of that country.

In many European countries the law of almost immediate burial is peremptory, by reason of the rapid decomposition of dead bodies in hot weather. And the New York *Evening Sun* observes that this requisite is likely to be taken unscrupulous advantage of. "When anything of oriental ingenuity is added to the overbearing quality too often inherent in the petty municipal officers, the situation of surviving relatives is serious particularly if no American or English consul not a native of the country can be reached immediately." It appears, however, that the oriental is not alone blameworthy; it seems, as we have seen, that he is equalled in our occidental civilization.

INFANT MORTALITY IN NEW YORK.

In view of the continued high infant mortality in New York, Health Commissioner Lederle has issued a statement to the effect that the responsibility for this is largely due to the ignorance or inattention of mothers. With babies dying at the weekly rate of 85 for every thousand in Manhattan and of 86 for every thousand in Brooklyn (the figures for the week ending July 23), he says that the great task of the Department of Health is to instruct mothers how to care for their infants, and (what is far more difficult) to get them to follow instructions. That the present high death-rate, notwithstanding the great heat of the summer, is unneccessary is shown by the results of a recent investigation by Dr. Guilfoy, the registrar of vital statistics. The latter has made a study of the conditions in a considerable territory in the middle west side of the city, where the people are intelligent and sufficiently well-to-do to give their infants proper attention, and finds that in three summers, in the district investigated, there was not a single death from infantile diarrhea. This result confirms the assertion of Dr. Joseph E. Winters, Professor of Diseases of Children in Cornell University Medical College, in a paper on Intestinal Infections in Children at the May meeting of the Medical Association of the Greater City of New York, to the effect that, with proper feeding and care, there is no more danger from this form of disease in summer than in winter. Dr. Guilfoy finds that the mortality has been highest among the negro babies, and ascribes this to neglect, racial rather than intentional, on the part of the mothers. Next in amount is the death-rate among the Italians, and then come the Russians and other foreign nationalities, in all of which the mortality far exceeds that among the native Americans.

In the meanwhile the Bureau of Child Hygiene, under the direction of Dr. Baker, with 150 medical inspectors, and as many nurses, is putting forth the most strenuous efforts in looking after the infants in the tenements and instructing mothers in proper methods of care. The mothers are supplied with simple rules for feeding and general care, and, in addition, with cards containing the location of the various milk depots where pure milk, kept at proper temperature, can be obtained at nominal prices, or free in cases of great poverty. They are also told to send for a physician or to notify the Health Department, (the telephone numbers of the branches of which are given) the moment that a child shows the first symptoms of illness. The statistics of the department show that while thus far the death-rate of the summer from infantile diarrhea has been considerably higher than in the corresponding period of last year, the mortality from this cause compares favorably with that of previous years in which the greatest mortality has occurred in the month of July. In 1909 this was unusually small. This year a much larger number of recreation piers and public playgrounds are in operation than ever before.

MEDICAL NOTES.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston.—For the week ending at noon, August 2, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 33, scarlatina 30, typhoid fever 18, measles 23, smallpox 0, tuberculosis 78.

The death-rate of the reported deaths for the week ending July 26, 1910, was 15.81.

Boston Mortality Statistics. —The total number of deaths reported to the Board of Health for the week ending Saturday, noon, July 30, 1910, was 216, against 202 the corresponding week of last year, showing an increase of 14 deaths and making the death-rate for the week 17.88. Of this number 122 were males and 94 were females; 213 were white and 3 colored; 145 were born in the United States, 64 in foreign countries and 7 unknown; 49 were of American parentage, 134 of foreign parentage and 33 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 34 cases and 2 deaths; scarlatina, 34 cases and 1 death; typhoid fever, 10 cases and 1 death; measles, 23 cases and 2 deaths; tuberculosis, 74 cases and 15 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 9, whooping cough 2, heart disease 22, bronchitis 1. There were 20 deaths from violent causes. The number of children who died under one year was 52; the number under five years, 72. The number of persons who died over sixty years of age was 59. The deaths in public institutions were 95.

Cerebrospinal meningitis, 1 case.

Of the above infectious diseases the following were non-residents: Diphtheria, 2 cases. Scarlet fever, 2 cases. Consumption, 6 cases and 1 death.

Deducting deaths of non-residents, the total is 189 and the death-rate is then 15.65.

BEQUESTS. —Through the will of the late George Dexter of Beverly and Boston the Free Hospital for Women in Brookline, Mass., receives $8000 and the Massachusetts General Hospital, $10,000.

By the will of Mrs. Julia M. Champlin of Brookline public bequests amounting to nearly $200,000 are made. Among the beneficiaries are the Home for Aged Men, Boston, $10,000; the Winchester Home for Aged Women, $10,000; the New England Peabody Home for Crippled Children, $5000. Other institutions likewise benefit after the death of certain beneficiaries.

A LOVING CUP FOR DR. RICHARD C. CABOT. — At the conclusion of a summer course given by Dr. Richard C. Cabot at the Massachusetts General Hospital during July a loving cup was presented him by his students who numbered forty. Dr. James C. Donohue, Dr. Cabot's assistant, also received a cup.

THE PRENDERGAST CAMP FOR TUBERCULOSIS. — The Boston Association for the Relief and Control of Tuberculosis conducts the Prendergast Camp. The object of the undertaking is to offer to men, whose tubercular process has been arrested, a place where they may live under the most favorable conditions, and so prevent, if possible, a relapse. The camp is near Mattapan, close to an electric car line and within the five cent fare limit. The men sleep in a "shack" open on the south side. There are proper bathing facilities, a living room, both of which are heated in cold weather, and a kitchen. The food is abundant and well cooked. The rate of board is $6.00 a week, in exceptional cases a lower rate will be accepted. It is not intended that this camp shall make a profit, nor that it shall be a charity, but it is intended that eventually it will be self supporting. The camp is primarily for men who are working, but this is not necessary. For those who are not there at dinner time, a dinner is put up which they can take with them to their work. The committee in charge has decided to admit some cases of tuberculosis that are not yet arrested, quiescent cases with a little cough or sputum, and who understand the need and methods of preventing the infection of others. Also incipient cases awaiting admission to sanatoria will be received. Preference will be given to men who are working, in the belief that many cases improve while at work, if they can spend half their time under proper sanatorium conditions. There will be no medical supervision, the patients remaining under the care of their own doctor. Arrangement has been made for calling a neighboring doctor, however, in case of an emergency.

Application should be made to the Secretary of this Association, Mr. Seymour H. Stone, accompanied by a medical statement of the present condition of the case.

NEW YORK.

BEQUESTS FOR CHARITY. — By the will of the late Henry Dexter, of New York, former president of the American News Company, more than a million dollars is left to religious and philanthropic objects, although most of the bequests do not go into effect until after the death of his daughter, Clarissa Treadwill Dexter. Among the bequests are $20,000 to the New York Association for Improving the Condition of the Poor, $10,000 each to St. John's Guild and the Charity Organization Society, and $1,000 to the New York Christian Home for Intemperate Men at Mount Vernon, N. Y. Charles S. Ward, of New York, who died recently, left the bulk of an estate of $160,000 in the form of trust bequests to relatives, with the provision that on their deaths the property shall be devoted to charity. Among the ultimate beneficiaries is the Presbyterian Hospital, which is to receive $10,000, besides a share in the residuary estate. Among the charitable bequests in the will of Mrs. Miles Standish Bromley, of New York, a sister of the late Mrs. William H. Vanderbilt, who died on July 4, is $3,000 to the Mothers' and Babies' Hospital.

8. Cyrian, E. F., and Cyriax, A. K. *The Manual Treatment of the Abdominal Sympathetic.*

7. Faught finds on investigation that observation of the blood pressure is far from universal in life insurance examinations. The chief reason given by companies is their lack of confidence in the ability of the average examiner to accurately observe and correctly interpret the reading. There are many factors which may cause material variation in pulse tension, e. g., posture, digestion, exercise, fatigue, mental excitement, alcohol. In spite of these sources of error the writer believes that the sphygmomanometer deserves a much wider application in life insurance work. [L. D. C.]

1. A brief summary of Weeks' views would be about as follows: In tuberculosis, benefit may be derived by use of the proper vaccine. Gonococcic vaccine is of undoubted value in chronic infections, but of no value in the acute stages. In streptococcic cases some cases are modified, but none cured; with staphylococcus the prognosis is good. Coley's toxin showed only one recovery, a case reported by Coley himself. With serums, the results are as follows: Diphtheria antitoxin is of undoubted value. Gonococcic serum is about equally effective with the vaccine. With streptococcic serum the results are variable. Tetanus cases are benefited if injected early. Cystogenic serums have been somewhat disappointing.

3. Hultgen, observing 460 cases of chronic alcoholism, concludes: (1) Alcohol when taken daily, as it is by chronic inebriates, dipsomaniacs or drinkers, is not an irritant to the kidneys. (2) When nephritis occurs in a chronic alcoholic, it is probably due to some other concomitant toxic agent, and not to alcohol. (3) Overeating, acute intoxicants, exposure to colds, auto-intoxications, infections either manifest or latent, and some metabolic disorders as yet unknown are the real causative factors of nephritis. (4) Alcohol when taken by drinkers as food or stimulant, such as we see in chronic alcoholism, is a diuretic. (5) Those tissues which eliminate alcohol are least affected by it. This applies to the lungs and especially to the kidneys. (6) Alcohol, while an intoxicant, is also a detoxicant, ridding the body of various deletorious catabolic products.

5. Bernheim, experimenting with extracts made from the thin coats of blood vessels, finds that there is seemingly in the blood-vessel wall itself a substance, which once the vessel is injured, probably aids in the formation of a clot.

6. Barton in his second contribution exposes more pharmacologic fallacies. He points out that lead and opium washes have no soothing value in sprains; that aconite taken internally does not quiet neuralgia; that spartein as a heart tonic has no value as a substitute for digitalis; that nitrohydrochloric acid has no value in diseases of the liver and jaundice; and that physiologic salt solution is not a heart stimulant *per se*. Calomel is not a cholagogue; ammonium chlorid, not an expectorant. All these may have some effect, but do not act *per se* as we are taught to suppose.

9. Matthews, as also Maury previously, has discovered in experimental work on dogs, that the duodenum exerts some influence, probably through the agency of a secretion, the removal of which from the body is incompatible with life.

12. Church finds in the monthly occurrence in nearly all males of various disturbances of mentality, digestion, sexual function, etc., evidence of a true climacteric in the male.

14. Pitzman maintains that bichlorid of mercury does not exert its reputed antiseptic action on the bacteria in the tissues for the following reasons: (1) It would have to exist in the tissues as excess free bichlorid, which is scientifically hardly conceivable. (2) If it existed as free bichlorid, it would destroy the body cells as well as the bacteria. (3) It is ordinarily not absorbed from a dressing.

17. These authors, experimenting on dogs, conclude that olive oil does seem to prevent the formation of adhesions in dogs and is worthy of a thorough trial in human surgery. Liquid petrolatum has but slight value for such a purpose. [E. H. R.]

The Lancet.

July 2, 1910.

1. *Mott, F. W. *The Oliver-Sharpey Lectures on the Cerebrospinal Fluid. Lecture I. The Physiology of the Cerebrospinal Fluid.*
2. *Andrews, F. W. *The Croonian Lectures on the Behavior of the Leucocytes in Infection and Immunity. Lecture II.*
3. Sinclair, W. J. *The Pelvic Conditions Resulting from the Slighter Forms of Puerperal Sepsis and their Treatment.*
4. *Philip, R. W. *The Tuberculous Gland: Its Significance and Treatment.*

9. Greenwood, M. *Poor-Law Medical Reform: What It Should Aim At.*
10. Hirsch, C. T. W. *Motoring Notes.*

1. In the first of the Oliver-Sharpey Lectures, Mott gives some historical remarks on the study of the cerebrospinal fluid, and then briefly describes its physical and chemical properties. He discusses the distribution, function and mechanical effects of this fluid.

2. In the second Croonian Lecture, Andrews discusses the functions of the polynuclear leucocytes and their dis-

tribution. He devotes the rest of the lecture to a consideration of leucopenia and the various conditions when this may exist, the mechanism of leucopenia and the constitutional symptoms associated with it.

4. Philip describes the changing point of view in regard to the wisdom of operating on all cases of tuberculous glands; twenty years ago this was considered the only treatment; to-day it is not so. Suppuration in a gland is relatively uncommon as compared with the occurrence of infiltration; in the greater number of cases it is but an incident which oftener than not does not take place. He describes what he considers to be the usual course of infection from the throat to the glands of the neck and thence, in many cases, to the thoracic lymphatics and to the lungs. As infection so frequently occurs in childhood he urges that children be taught to care for their teeth and throats in a most careful way. He discusses the limitations of operative treatment and the great value of vaccine therapy, with remarks on procedure and dosage. He concludes: (1) Watch for the earliest indication of involvement of lymphatic glands in young children and regard such as certainly of a tuberculous nature. (2) Treat the throat and mouth locally and in general by tuberculin. (3) If there be suppuration, evacuate it in simple fashion, but continue the use of tuberculin. [J. B. H.]

JULY 9, 1910.

1. *MOTT, F. W. *The Oliver-Sharpey Lectures on the Cerebrospinal Fluid. Lecture II. The Pathology of the Cerebrospinal Fluid.*
2. *ANDREWES, F. W. *The Croonian Lectures on the Behavior of the Leucocytes in Infection and Immunity. Lecture III.*

4. *KRAUS, C. *The Examination of Feces in Medical Practice.*
5. FAULDER, T. J. *The Administration of the Public Health and Education Acts in Relation to the Prevention and Cure of Diseases of the Throat and Nose.*

1. In the second of the Oliver-Sharpey Lectures, Mott discusses the pathology of the cerebrospinal fluid and its chemical alterations in disease and the varieties of abnormal changes which the fluid may undergo. He especially dwells on those changes occurring in sleeping sickness, syphilis and parasyphilis, with remarks on the value and technic of the Wassermann reaction.

2. In the third of the Croonian Lectures, Andrews describes a series of animal experiments of infective conditions produced by intravenous inoculation. He discusses the relationship of leucopenia and anaphylaxis, the nature of anaphylaxis, with observations on immunity in the anaphylactic animal. He then discusses those conditions in which the leucocytes are increased, and the various types of leucocytes.

4. Kraus describes the development of scientific examination of the feces as an essential factor in rational treatment of disorders of the stomach and intestines. Before examination of the feces in any given case he puts his patient on a trial diet for forty-eight hours, which must include milk, eggs, meat, farinaceous food, green vegetables, stewed fruit and fat. He goes on to describe the various tests, microscopic, macroscopic and chemical, which should be made in every case. [J. B. H.]

8. PAVY, F. W., AND BIGWATERS, H. W. *On the Presence of Sugar in Healthy Urine as a Source of the Osazone Reaction.*

2. Starr quotes figures from the Massachusetts General Hospital and elsewhere which show that the present state of the treatment of fractures is in anything but a satisfactory condition. Especially in fractures of the femur and in both bones of the leg, in at least 30% the result was unsatisfactory, some paramount deformity resulting. He urges a more frequent resort to the open operation by which the broken bones can be accurately set and then plated.

3. Ward discusses the difficulty in accurate diagnosis of urinary disease under three headings: (1) The similarity of symptoms in disease of different parts of the tract; (2) reflex or transferred symptoms; (3) absence of any localizing symptoms. Among the methods of accurate diagnosis he discusses the use and value of the cystoscope, catheterization of the ureters, radiography and others.

4. Fullerton gives the details of 24 cases of renal tuberculosis whose subsequent history he has followed up. He discusses these cases as regards early diagnosis and treatment.

6. Hamburger, in a brief article, gives statistics based on a study of 532 patients suffering with scarlatina or diphtheria, with a view to the incidence of tuberculosis in those children. He concludes: (1) The majority of persons become infected with tuberculosis in childhood. (2) The frequency of such infection increases from year to year, while tuberculous morbidity, the frequency of manifest tuberculous disease, decreases. (3) Tuberculosis is very commonly latent, producing no symptoms. (4) The older the person is at the time of first infection, the better is the prognosis. [J. B. H.]

13. Lang. *Postscript to the Article by Professor Lang on Lupus in the Preceding Number of this Journal.*

3. Sleeswijk, in trying the Noguchi test for syphilis, concludes that in cases of undoubted syphilis this test is as accurate as the Wassermann reaction. In certain cases of fever, and doubtful cases, the Noguchi reaction was positive when the Wassermann reaction was not. He concludes, therefore, that the Noguchi reaction is no improvement on the Wassermann because it is not as reliable.

7. Mendel has been using tuberculin intravenously now for over one thousand doses and has never seen any ill effects. The constitutional symptoms after its use are roughly the same as after subcutaneous inoculation. As a diagnostic means he considers it as effective as any of the other methods. From a therapeutic standpoint he considers it more effective, especially if given in combination with atoxyl in intravenous injections. [C. F., Jr.]

7. Koslow. *Ether-Acetone Combination of the Antiformin Method in the Identification of Tubercle Bacilli.*
8. Hoffmann. *The Malarial Conference in Simla.*

5. The author shows by careful descriptions and by a series of photographs that with diseases involving only one lung, especially where the pleura is also involved, there is frequently a definite lymphatic stasis limited to that side of the body. This stasis can be readily seen and felt by an increased turgidity of the tissues. This is not confined to half the thorax only, but is evident in the face, abdomen and upper arm. He concludes with a theoretical discussion of the reason for this stasis and its value as a diagnostic sign of intrathoracic disease.

5. *Axisa, E. *The Treatment of Amebic Dysentery.*
6. von der Porten, E. *The Treatment of Delirium Tremens with Veronal.*
7. Ritter, C. *An Old Forgotten Hyperemic Method.*
8. Muskat, G. *Dysbasia (Intermittent Lameness).*

5. Axisa reports a number of cases of acute, subacute and chronic amebic dysentery from the Austro-Hungarian Hospital in Alexandria. He finds Kossam a valuable remedy, especially in uncomplicated cases of long standing; some of his cases which had resisted other treatment for years yielded in a few weeks. In some instances the action of this drug was as specific as that of quinine in malaria. Kossam is the oily seed of bruces sumatrana and has long been a popular remedy for dysentery in Cochin China and elsewhere in the Orient. The active principle is a glucoside, kossmine. It acts directly on the amebæ; bleeding is promptly stopped and subjective symptoms relieved. In acute cases an occasional purge should be given. If the stools remain thin and watery after mucus and amebæ have disappeared, astringents per rectum are indicated, e. g., 0.5% tannic acid solution. [L. D. C.]

5. Petacci, A. *Researches on the Romanowski Stain and a Quick Method of Using It.*

2. Ascoli studied malarial pigmentation by experiments on dogs. He was able to collect from the spleens of pernicious cases a certain amount of pigment which could not be obtained from the spleens of animals poisoned with pyrodin. The coloring matter was demonstrated by its chemical properties and by spectroscopic examination to be hematin, which is produced from hemoglobin by the action of the parasite. The properties of this pigment vary with the phases of the life cycle of the plasmodium. The degree of cachexia in malaria depends not upon the quantity of pigment produced, but upon the species of hematozoon harbored. The pigment is formed for the most part in the spleen and the bone marrow where the parasite completes the last phase of its asexual life and most of the phases of its sexual life. Pigment is present in the blood stream in small amounts only and quickly disappears. [L. D. C.]

Correspondence.

DUBLIN LETTER.

Obstetrics in Ireland. Tuberculosis. Anti-vaccination Agitation.

Dublin, July 13, 1910.

Mr. Editor: Though Ireland ought perhaps hardly to be called the home of obstetrics, it is surely a country

where, in the hospitals at least, the science and the art of obstetrics are taught and practised in very classic and conservative form. This is due in part probably to the insular character of the local civilization in which changes, though intelligently made, come slowly and without disestablishment of long-existing custom, and partly to certain well-marked racial physiologic characteristics of the people. It is a common saying in our own obstetric clinics in Boston that "the Lord loves the Irish," and in the matter of childbirth this seems to be true in the old country as well as in the new.

Our first experience of Irish obstetrics was in the city of Cork, at the Erinville Lying-In Hospital, a small but well-managed institution, conducted essentially on the principles of the Dublin Rotunda, and by a graduate of that hospital. The Erinville is pleasantly situated on one of the principal streets, and contains four public wards, "open day and night, free of charge, to respectable married women, without religious distinction, who must be recommended by a clergyman, doctor, or Lady Governess." It also has semi-private wards, in which patients pay twenty shillings a week, and a private room, not often occupied, we were told, for which the weekly fee is three guineas. The building is old, probably several hundred years, but shows, within and without, a capacity of adaptation to modern requirements which makes really good work possible even in an archaic environment. The principles of aseptic surgery and obstetrics are often all so very simple that understanding and conscience are the only essentials for their fulfilment, as in *Hamlet* "the readiness is all."

During the year 1909, 385 patients were admitted to the Erinville Hospital, of whom 333 were delivered. In the externe department, 180 women were attended at their own homes. Among the 565 patients thus cared for, there were only two maternal deaths, one from advanced heart-disease, one from secondary post-partum hemorrhage. The total infantile mortality was 19, 6 of these being macerated fetuses and 5 premature. Considering the life and surroundings of most of the patients, and the conditions under which much of the work must be done, these figures furthur illustrate the truth of the proposition that "the Lord loves the Irish."

In the hospital all the normal deliveries, which means a very large proportion, are conducted by the pupil nurses under the direction of the resident matron, who is a sort of combination of superintendent, head-nurse and house-officer, and an extremely capable woman. In the externe department, patients are attended by licensed midwives, graduates of the Dublin Rotunda or of the Erinville training-school, which receives yearly "a limited number of women to be trained as obstetric nurses and granted certificates when the medical staff are satisfied of their competency." As at the Rotunda, the term of study for such probationers is six months, "and the fee, including board, practise and instruction, £16." For nurses who have previously had "a satisfactory hospital training," the term is only three months and the fee £10. To one accustomed to our American training-schools where nurses are paid, howbeit scantily, it seems as surprising that they should be thus charged a fee as it does to learn that the medical staff at the Rotunda, from the Master down, pay a really considerable sum for their appointments, though the mere possession of wealth without qualification will not secure such appointment. In the old world opportunity for instruction and experience is still difficult enough of attainment to be really valued by those who get it. As long as this remains true, nurses will doubtless continue to pay fees to the training-schools. Until it ceases to be true, however, or until financial and educational conditions are largely modified, it will be impossible in Ireland to require of obstetric nurses, as is done in our best schools, a previous general hospital training, followed by six months obstetric pupillage, or, in the absence of such previous training, a fifteen months' course of obstetric instruction.

Medical students, the bane and *bête-noire* of our selfish American house-officers,— themselves barely out of studenthood, — are allowed to attend visits and demonstrations by the medical staff and occasionally to conduct deliveries, interne and externe. At Erinville they are nearly all members of Queen's College, Cork, now a national university. There is much less operative obstetrics for them to see than in American clinics, partly on account of our greater impatience and *fames operandi*, partly on account of the racial physiologic characteristic, already alluded to, which make normal labor much more often the rule in Ireland than the exception. At Erinville, as at the Rotunda, an expectant policy is pursued; patients are allowed to go much longer unassisted in the second stage than is our custom; and the visiting staff are summoned only for complications or prolonged dystocia, with good results that would be impossible in a clinic of different social or mixed racial composition. Puerperal complications, too, are rare: tonsillitis, otitis media, phlebitis and mastitis seem practically not to occur; and a puerperal temperature over 100° almost invariably means and is treated as uterine infection. That these cases, also, are very infrequent is evidence of the efficiency of the nurses' work, and it is to the immense credit of Irish obstetrics that it has so practically taught the principles of asepsis as to obtain their successful application under the most disadvantageous conditions.

Not all the problems of obstetrics, however, are successfully solved in Ireland. As in all other countries, the mortality from puerperal sepsis, outside of hospitals and teaching clinics, still remains unduly high, and is even greater in Ireland than in England and Wales. This is because unlicensed midwives still practise in Ireland. There has been of late considerable agitation, medical and popular, over the proposed extension to Ireland of the provisions of the British Midwives' Act, which requires examination and registration of all midwives in England, and forbids unregistered midwives to practise. Late in June a conference was held of representatives of the Irish Medical Society, of the Royal Colleges in Ireland, of the Royal Irish Academy of Medicine and of various other professional bodies, who voted unanimously to support the demand for such extension. In a letter published in a recent issue of the *Medical Press and Circular*, Sir William J. Smyly, of Dublin, a former Master of the Rotunda, strongly advocates this resolution, and in argument cites the fact that in England and Wales the death-rate from puerperal fever in private practise has steadily declined since a uniform Midwives' Act went into effect. He further points out the injustice now done the licensed midwives of Ireland, who not only have to compete with unregistered midwives in Ireland, but are not themselves allowed to practise in England. The remedy for this condition, he believes, is either the proposed extension of the British act to include Ireland, or a separate Irish Midwives' Act with standard requirements and reciprocity between the two countries. The problem of midwives is one that fortunately has not yet assumed serious importance in the United States, and probably is hardly likely to do so. Its present prominence here emphasizes an aspect of obstetrics with which we are happily but little familiar.

At Dublin, the center of obstetric interest, is of course, the Rotunda, but equally important and worthy of a visit are the Coombe Maternity and Sir Patrick Dun's hospital, which one cannot help wanting to associate somehow with Sir Patrick Spens. We were everywhere handsomely received, with fraternal professional cordiality and the graciousness of true Irish hospitality. It was rather interesting and surprising, by the way, to find the two Assistant Masters at the Rotunda one a Pennsylvanian, the other an orthodox Jew. It was also surprising to learn that the old gray weather-beaten round building from which the hospital derives its name, — and which one had always imagined as originally filled with patients' beds ranged around the wall and later perhaps used for lectures and demonstrations, — that this was never used obstetrically at all, but was built by the governors as a hall to be let to the public for dances, concerts and other entertainments, to furnish revenue for the maintenance of the hospital. For many years the Rotunda was the scene of all the gayest functions of Dublin society, and though it has somewhat lost caste of late, it is still used and furnishes a valuable source of income. At present it is lavishly placarded with posters of a mammoth Hibernian Bazaar to be held there the latter part of July. Similarly, within a few years, the governors have erected in the spacious secluded gardens of the hospital a large covered skating-rink, which is let to a private company

who maintain it and charge the public a fee for admission which nets a profit both to the company and to the governors. The need of hospital economy and thrift is not unknown in America, but we are hardly yet accustomed to the idea of the trustees of our institutions running public amusements in hospital buildings as a business venture.

In Ireland, as on the European continent, there prevails and is accepted as a matter of course, the theory that obstetrics and gynecology are but different aspects or departments of the same subject and should be taught and practised together and by the same persons. All the larger maternity hospitals have gynecologic wards to which are admitted not only patients with troubles consequent upon parturition, but women with pelvic disease of any sort. At the Rotunda, about five hundred such interne patients are treated annually, besides a large amount of minor, non-operative gynecology done in the externe department. The concept of the essential unity of obstetrics and gynecology is one that unhappily seems at present not yet fully established in America.

It is from the gynecologic surgery that the pathologist at the Rotunda derives the majority and the most interesting part of his material. Morbidity and mortality are rare in the obstetric wards. In the year 1908–09 there were but 4 maternal deaths among over 2,000 patients, and the pathologist was called upon to examine cultures from only 35 cases of suspected uterine infection, of which 15 proved negative. Autopsies are done on all fatal cases as a matter of course, there being no requirement of permission, as in our country, to hamper the pursuit of medical study. Another instance of the infrequency of puerperal complications is the fact that among over 2,000 patients last year there were but 7 cases of eclampsia, who all recovered, and only 2 of mastitis. The rarity of breast infection may be partly explained by the custom of letting all normal cases leave the hospital on the eighth day, but this cannot account for it altogether, and, like the rarity of eclampsia, it must be attributed in part at least to racial physiologic habit.

There is so much to see and to say about the Rotunda, that it is impossible to tell it all here. It is an unfailing source of interest and pleasure and inspiration to go about the wards with the master, to listen to his keen comment and trenchant criticism as he instructs his students, to watch him and his assistants at operation, to observe and compare points in which their method and technic differ from ours. The elements of asepsis are of course the same the world over, though it sometimes seems that the greater elaborateness of detail observed here must introduce possibilities of error which our simplicity avoids. In the operating-room the most striking single thing is that patients for pelvic laparotomies are placed in a combined Trendelenburg and lithotomy position, and the operator stands most of the time between the patient's legs, his assistant being on one hand, the operating nurse on the other. This method has at least one great advantage, that the surgeon can address his audience and demonstrate his work to their much better satisfaction. In the obstetric wards it is chiefly noticeable that forceps are applied and breeches delivered with the patient in the left Sims position, instead of on the back, procedures said to seem easy and natural to those who practise them, though appearing very awkward to us, and probably like most details of technic representing individual custom and habit rather than intrinsic difference of merit. The third stage is treated more conservatively and deliberately at the Rotunda than is often our practise, and the uterus is not nearly so strenuously controlled. Yet post-partum hemorrhage is not so frequent as in our clinics. Is this another instance of happy racial physiologic adaptation? "Did you have the first baby yourself, or did the doctor have to use instruments?" said the master to a woman whom he was examining for contracted pelvis. "Sure I had it meself," she rejoined, half indignantly, half humorously, "I'm Irish!"

Let it not appear, however, that there is nothing of medical interest in Ireland but obstetrics. The problem of pulmonary tuberculosis is one of the most important with which the profession has undertaken to deal, though, perhaps on account of climate, the racial susceptibility of the Irish to this disease does not seem to be so high here as it is in America. During the past ten years there has been in Ireland a great popular awakening to the nature of consumption and the possibility of its cure and prevention, largely due to the extensive educational campaign instituted and carried out by Lady Aberdeen. The results of her work may be seen not only in the establishment of sanatoria for tuberculous patients, in the improvement of housing conditions among the poor, and in the conspicuous posting of notices forbidding promiscuous expectoration, but also in the general frequency with which one observes wide-open windows, particularly in the early morning while most people are still asleep. Though the ventilation of many hovels and cottages is still abominable, the fresh-air theory seems to have got a foothold, and in the daytime nearly everyone lives outdoors anyway. In Dublin, two special tuberculosis nurses, maintained by the Women's National Health Association, spend their time among the poor, caring for those who have phthisis, and teaching others the principles of prophylaxis. Plans are also in progress for the erection in Dublin of a special Dispensary for the Prevention of Consumption. Notwithstanding such advances, however, much still remains to be done. At a recent quarterly meeting of the Dublin Hospitals' Tuberculosis Committee it was unanimously resolved that, in the opinion of the committee, "a large proportion of chest affections leading to tubercular disease in the city of Dublin is due to the excessive amount of dust in the streets, the inadequate watering thereof, and the faulty method of street-sweeping." The committee further "notes with regret that the plague of dust is especially prevalent in the poorer quarters, where little or no attempt is made to lay it by watering and subsequent removal." As a matter of fact, the streets in Dublin, and in Ireland generally, do not seem a bit dirtier than many in our own Boston, though it is true that street-watering and sweeping are not nearly as thorough as in our city. Cleanliness is no more an American than an Irish trait, and the ill-discipline of the average American nakes him an all too frequent offender in the scattering of street-litter.

Another problem of medical interest, over which there seems to be considerable agitation in Ireland at present, is the question of compulsory vaccination. Apparently, in Great Britain, vaccination is optional, and parents who have a conscientious objection to it are not compelled to have their children inoculated. In Ireland, however, the law is absolute, and those who seek to evade it are punishable by fine. In a letter to the *Cork Examiner*, a correspondent, evidently an opponent of vaccination, eloquently describes "the terrible and ghastly dangers inseparable from vaccine blood-poisoning," and relates the case of "a child who was 'stone-blind' and yet, shameful to relate, the law demanded that in addition to the terrible affliction of blindness there should be imposed upon it the filthy, torturing disease of cowpox, a disease of such malignancy that many strong men have been slain by it." He further expresses the hope "that the people of Ireland will give their representatives in Parliament no peace until they at least stand on an equality with their English, Scotch and Welsh brethren in this matter; or, better still, not until every remnant of this obnoxious compulsory vaccination law is swept from the statute book." Apart from differences of opinion as to the advisability of compulsory vaccination or as to the lethal "malignancy" of cow-pox, this letter is a straw that shows which way the wind of public opinion is blowing. It must be admitted that there is some justice in the correspondents' plea for equality, and it must be remembered that doubtless vaccination has been brought into popular disrepute in Ireland, as among some persons in America, partly through the improper practise of it by certain physicians whose intentions have been better than their asepsis.

In this connection it is interesting to compare some statistics recently published in the annual report of the Metropolitan Asylums Board for 1909, giving the mortality from smallpox in London since 1838. In that year there were 3,817 deaths from the disease among a population of 1,800,000, a rate of 2,120 per million. The death-rate then declined steadily till 1871 when, in conjunction with an epidemic, it rose to 2,422 per million. Since then it declined more rapidly, and in the years 1906, 1907 and 1908 there was actually not a single death from smallpox in the city of London, with a population nearly three times as

great as in 1838. In 1909 there were 2 deaths from smallpox in London, and in the first three months of 1910 only 8 have occurred in the whole of England and Wales. Ingeniously enough, the opponents of compulsory vaccination undertake to explain this decreasing mortality by the increase of conscientious objection to vaccination, and point out, in support of their contention, that the three years in which there were no smallpox deaths in London, the percentages of exemption for such objection were respectively 5.6, 6.2 and 17.2. In commenting on this absurd reasoning, the *Medical Press and Circular* appropriately remarks: "The *suggestio falsi* and *suppressio veri* involved in this line of argument is grotesquely apparent, and shows to what depths of intellectual squalor the anti-vaccinationists must have fallen." In an address before the Conference on Tuberculosis recently held in Edinburgh in conjunction with the annual meeting of the National Association for the Prevention of Consumption, Dr. Osler also took occasion to refer to the pernicious activity of anti-vaccinationists. He is reported to have said that in the event of a severe epidemic of smallpox he should like to issue them a challenge for the simultaneous exposure, in the care of the sick, often selected vaccinated persons and ten selected unvaccinated persons, — the latter preferably members of Parliament and anti-vaccination doctors and propagandists, — with the promise "neither to jeer nor to gibe when they caught the disease, but to look after them as brothers, and for the four or five who would be certain to die, to arrange a funeral with all the pomp and ceremony of an anti-vaccination demonstration." If the humor of this suggestion be half American, it serves to illustrate the better that other English-speaking countries are no freer than we from the lets and hindrances that impede the progress of medical service to the community, and makes us more appreciative of our professional good fortune in some respects at home by comparison with the troubles of others abroad.

Medicus Peregrinus.

RECORD OF MORTALITY

For the Week ending Saturday, July 23, 1910.

Cities.	Reported deaths in each.	Deaths under five years.	Cities.	Reported deaths in each.	Deaths under five years.

LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND OTHER OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED JULY 27, 1910.

Wasdin, Eugene, surgeon. Granted one month's leave of absence from July 22, 1910, on account of sickness.

Eager, J. M., surgeon. Granted seven days' leave of absence from July 21, 1910.

Nydegger, J. A., surgeon. Leave of absence for seven days from July 3, 1910, amended to read on account of sickness, in accordance with paragraph 202, Service Regulations.

Wickes, H. W., passed assistant surgeon. Directed to proceed to Washington, D. C., and report to chairman of board of medical examiners to determine his fitness for promotion to the grade of surgeon. July 20, 1910.

Holt, John M., passed assistant surgeon. Granted seventeen days' leave of absence from August 11, 1910, and nineteen days' leave of absence from September 1, 1910.

Glover, M. W., passed assistant surgeon. Granted ten days' leave of absence from July 25, 1910.

Lloyd, B. J., passed assistant surgeon. Granted one month's leave of absence from July 20, 1910, on account of sickness.

Roberts, Norman, passed assistant surgeon. Granted one day's leave of absence July 21, 1910, under paragraph 191, Service Regulations.

Pettyjohn, Joseph, passed assistant surgeon. Granted one month's leave of absence from August 15, 1910, on account of sickness.

Knight, C. P., assistant surgeon. Granted seven days' leave of absence from July 18, 1910, under paragraph 191, Service Regulations.

Gray, E. George, acting assistant surgeon. Granted seven days' leave of absence from July 25, 1910.

Onuf, B., acting assistant surgeon. Granted four days' extension of leave of absence from July 17, 1910, on account of sickness.

Safford, M. Victor, acting assistant surgeon. Granted ten days' leave of absence from July 20, 1910.

Seavey, L. T., acting assistant surgeon. Granted twenty-one days' leave of absence from August 8, 1910.

Walker, Thomas D., Jr., acting assistant surgeon. Leave of absence for eleven days from June 28, 1910, amended to read eight days from June 28, 1910.

Rogers, Edward, pharmacist. Granted seven days' leave of absence from July 14, 1910, under paragraph 210, Service Regulations.

CHANGES IN THE MEDICAL CORPS U. S. NAVY DURING THE WEEK ENDING JULY 30, 1910.

Rhoads, G. C., assistant surgeon. Ordered to duty at the Naval Hospital, Norfolk, Va. July 22.

Bloedorn, W. A., assistant surgeon. Ordered to the Navy Yard, Mare Island, Cal. July 23.

Downey, J. O., assistant surgeon. Detached from the Naval Hospital, Norfolk, Va., and ordered to duty at the Naval Hospital, Naval Home, Philadelphia, Pa. July 26.

AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION.

The American Electro-Therapeutic Association will hold its Twentieth Annual Meeting at Saratoga Springs, New York, September 13, 14, and 15, 1910.

RECENT DEATH.

Dr. Frederick W. Lilienthal, of New York, died at his country residence in the Catskills on July 28, at the age of seventy-seven years. He was a native of Germany, and was graduated from the University of Berlin in 1858. He came to this country in 1861, and built up a large practice among the German population of New York. He was one of the founders of the *New Yorker Volkszeitung*, and was a prominent member of the International Socialist Union.

Original Articles.

THE CLINICAL ASPECTS OF ARTERIOSCLEROSIS.*

BY HENRY JACKSON, M.D., BOSTON.

THE subject of arteriosclerosis is one that interests us all in that it represents a condition that all of us who live long enough must sooner or later come to. The etiology is obscure and the pathologic processes dependent upon the condition are most varied. Clinically, the symptoms are as varied as are the pathologic processes which may result from changes in the vessel walls.

The marked changes in the larger vessels were recognized by the older anatomists and clinicians, but the importance of these changes was not appreciated until a comparatively recent time, some forty years, or until the work of Gull and Sutton in 1871–72. These authors were the first to recognize the important rôle in the etiology of disease played by fibrous changes in the walls of the smaller arteries, their so-called arterio-capillary fibrosis. For instance, Walshe, in his book, "Diseases of the Lungs and Heart," published in 1851, says "Atheroma and calcification of the aorta, conditions of great anatomical interest, have in themselves but little importance." Also in his discussion of the cause of angina, though he expresses the opinion that there must be some organic cause for the trouble, he does not mention the rôle of changes in the vessels as causative of the disease.

Pathologically, we find changes in the elastic tissue of the vessels, in the media and in the intima. As the changes in the intima are the most prominent features, so this factor was first noticed by the pathologists, and we find in the older books of pathology an accurate description of changes which have taken place in the intima, as atheroma, calcareous degeneration and colloid changes. These changes were well recognized before the changes in the smaller vessels were known, and when but little clinical significance was attached to atheroma of the aorta, for instance. It is now known that the primary process is found either as a degenerative or as an inflammatory change in the media, or perhaps some defect or strain of the elastic fibres. The marked and long recognized changes in the intima, on the other hand, represent a conservative process, a protective cement, so to speak, to guard against injury of the arterial wall because of the disease in the media. As Dr. Councilman has said, an atheromatous process represents "a degeneration in the media and a growth in the intima."

It is to me a deplorable fact that the laity are so conversant with and talk so much about hardening of the arteries without, of course, any idea of the significance of the changes in the specific case under consideration. We are all of us often asked whether we think the arteries are hardened, and in many cases we can truly say, yes, the arteries have changed just as the appearance of the skin has changed, but the arterial change means no more than the hardening of the skin means, a mark of advancing age. I often say to a patient that if a hand were pushed through a sheet he could at once say whether it was the hand of a man of twenty-one or fifty-one years; so the physician can discriminate between the arteries of a man of twenty-one or fifty-one years, though a decision as to the results of such arterial changes is a very complex matter, leading often into regions unexplored and always obscure.

In the sixth volume of the Transactions of the Association of American Physicians, Dr. Councilman published a very valuable article on arteriosclerosis, in which he describes what may be called the clinical-pathologic types of this disease; he makes three divisions.

(1) Nodular form, seen especially in the aorta, often of no importance clinically, and usually giving rise to no symptoms, except in the rather rare instances where such a pathologic change is the primary factor in the causation of aneurism.

(2) Senile type. In this form the vessels are often calcareous; the heart is small and the liver and kidneys show only the atrophy which accompanies old age.

(3) Diffuse arteriosclerosis. This is the type which gives rise to the serious types of disease from a clinical point of view, which is meant when the laity talk about hardening of the arteries. This is the disease which is the cause of many so-called cases of Bright's disease and practically all cases of "cardio-renal" disease.

Of the first, or nodular form, I shall not speak in that it does not give rise to clinical symptoms.

The second, or senile type, is of great interest from the point of etiology; the heart is not enlarged. Clinically, we often see arteries which feel like broken pipe-stems, and so hard that it seems as if they would crack if they were out of the body. We find these conditions in the very old, in people who are essentially well except for such ills as are dependent upon general debility of a senile type. The heart is often extremely intermittent and irregular, yet does not show the results of heart failure as evidenced by edema of the extremities, by congestion of the liver or kidneys, or even chronic bronchitis with varying grades of pulmonary edema. It is not my experience that such individuals are especially subject to apoplexy or other diseases which could be attributed to the diseased condition of the arteries.

It is hardly conceivable that the same etiologic factors underlie this form of arterial disease as are considered the probable cause of diffuse arterio-capillary fibrosis. It certainly suggests that in the latter type there is some toxemia, as yet undetermined, which is a powerful factor in the production of the widespread diffuse fibrous degeneration of the arteries seen in the third and all important type of diffuse arteriosclerosis.

Yet in the senile type we find many symptoms probably directly attributable to the condition of the arteries, rather local disturbances in the circulation than disease which affects the body as a whole.

* Read at The meeting of The Massachusetts Medical Society, June 7, 1910.

The third type of Dr. Councilman, diffuse arteriosclerosis, represents a pathologic condition which is of the greatest importance from its being the direct cause of many very varied pathologic conditions, as it has given rise to much discussion as to its etiology, and as it is the cause of many clinical symptoms or signs as different one from the other as cerebral hemorrhage, muscular rheumatism and heart disease.

Attention of clinicians was first permanently drawn to this disease by Gull and Sutton in 1872, though their chief attention was directed to the kidney lesions dependent upon arteriosclerosis.

Diffuse arteriosclerosis is a disease found especially and in its most marked type in individuals otherwise healthy, often of robust type and full blooded, who are from forty to fifty years of age; it may be found in much younger people, but it is most common in those advanced in years. The heart is enlarged, weighing on the average 400 gms. or more; in this form of heart disease we find the largest hearts, cases being on record of hearts weighing over 800 gms., when there was no valvular disease. The dilatation of the heart may be so great that all of the valves become incompetent, so that murmurs may be heard at all of the orifices of the heart without the presence of any disease of the valve curtains.

The kidneys are usually diseased as shown clinically by the presence of albuminuria with casts. When the heart is seriously affected, as is seen in so many cases, the question always arises what signs may be attributed directly to the sclerosis and what to the secondary disease of the heart. From an etiologic point of view many conditions must be considered, though clinically the most satisfactory classification is that of Osler who thus describes three great divisions of arteriosclerosis, namely: "Normal wear and tear of life, acute infection, intoxications and those combinations of circumstances which keep the blood tension high." In the last few years many experiments have been made in the attempt to produce in animals lesions similar to arteriosclerosis in man, but though such experiments have successfully produced types of sclerosis closely allied to certain types of sclerosis in man, most investigators are still in doubt whether the lesions are produced by the artificially increased blood pressure or by some toxic property inherent in the drug used to cause the increased pressure.

In 1889, the first reported animal experiments were made by Lion and Gilbert: they used intravenous injections of bacteria or bacterial toxins to produce sclerosis. In 1902, Von Eiselsberg reported similar changes in thyroidectomized animals. In 1905, Pearce and Stanton succeeded in producing definite sclerotic lesions by the use of adrenalin; they used twenty rabbits; nine died from poisoning by the adrenalin, but six of the eleven who survived showed lesions of sclerosis. In one case Pearce and Stanton report their results as follows: "The media is firm, parchment like, and so distinctly calcified that the vessel cracks in several places when the arch of the aorta is straightened." The histologic picture they describe as follows: "The most striking feature of the late histologic picture is the extent of repair in the intima. The latter with its newly formed connective tissue and elastic fibrils becomes so greatly thickened, that it constitutes in some places a quarter to a third of the entire vessel wall and offers convincing evidence of the compensatory nature of the repair process."

These lesions were produced in animals in the course of sixteen to sixty days by injection of adrenalin every other day, a drug which produced a definite rise in blood pressure, but a rise in pressure of very short duration, so that Pearce and Stanton as well as subsequent investigators express doubt whether the pathologic condition was the result simply of the increased pressure or of some toxic substance in the adrenalin acting entirely independently of its power to temporarily increase blood pressure.

Their results are especially interesting as favoring the generally accepted view that the primary disease lies in the media, and that the process so prominent in the intima is secondary and essentially of a conservative nature.

In 1906, J. L. Miller reported the results of his work in the production of sclerosis in animals. He agrees with Pearce and Stanton that the primary disease is in the media and that the intima and adventitia are not involved except in the process of repair, the defects in the wall being repaired by cells arising from the intima. Dr. Miller reviews the various substances used to produce experimental arteriosclerosis as digitalin, nicotine, lead salts, adrenalin, and adds two others physostigmin and barium chloride. He also considers that the question is not proven whether the exciting cause of the disease lies in the power of the drug to raise the blood pressure or in some toxic property independent of this power.

In 1906, Charles S. Bond, of Richmond, Ind., made to the Association of American Physicians a most interesting communication from a clinical standpoint as to the etiology of arteriosclerosis. For twenty years he followed the course of 150 cases of chronic indigestion with over indulgence in food, and selected 100 from which to draw conclusions. All cases were omitted in which there was alcoholic excess or a possible chance of syphilis. In these cases there was an excess of food, deficient motor power of the stomach, and constipation. Thirty per cent. developed arteriosclerosis in a more or less marked degree, 5 died of angina, 6 of apoplexy and 4 of cerebral hemorrhage, while the remaining cases were under observation and all showed varying grades of increase of arterial tension and abnormal heart action.

To certain toxic agents we may very surely attribute an important rôle in the causation of arteriosclerosis; alcohol taken in the form of hard liquor and used continuously, though not in quantities to cause intoxication, is, from clinical observation, a most important etiologic factor. Lead is another, yet neither of these substances raises the blood pressure. Syphilis produces a specific form of disease of the arteries which is recognizable by

the pathologist. Experimental work has shown that bacterial toxins may cause sclerosis.

Dr. W. S. Thayer has studied especially the influence of typhoid fever on the arteries. In 52 autopsies he found arterial changes in 30, in 21 of which the lesions were evidently fresh and presumably due to the toxin of the typhoid fever. Also he found changes in the coronary arteries in 62 cases, in 19 of which the lesions were evidently fresh in thirteen.

From experimental and clinical observations it seems probable that we must attach greater importance to the rôle of varying toxic processes associated with acute infectious diseases in the etiology of arteriosclerosis. Yet the chief cause probably lies in overeating and consequent gastro-intestinal disturbance.

The theories suggested offer certainly a possible explanation of the etiology of the two distinct clinical types of arterial disease which we see. The one, a calcareous degeneration of the arteries seen in old people, subject only to the ordinary though perhaps strenuous wear and tear of life, in individuals who do not appear to suffer from the arterial changes. On the other hand, we have the cases of diffuse arteriosclerosis in younger persons, who suffer most severely from varying secondary pathologic processes, a disease probably toxic in etiology.

The clinical symptoms of arteriosclerosis differ as widely as do the pathologic conditions, and may be divided into symptoms due to localized interference with the circulation, and symptoms due to general obstruction of the whole arterial system as in diffuse arteriosclerosis, with secondary enlargement of the heart.

The symptoms dependent upon arteriosclerosis may then, from a clinical standpoint, be divided into localized symptoms and general symptoms, and I first take up the localized symptoms as these are perhaps less generally recognized than the more severe types of disease dependent upon widespread capillary fibrosis.

Localized symptoms. — The most important, perhaps, are those associated with disease of the vessels of the heart. In many cases of sclerosis of the arch of the aorta we find an extension of the process to the valves of the heart resulting in sclerotic changes of the aortic valves. Such changes are recognized by an irregularity in the aortic second sound often with a slight systolic or diastolic murmur according as the lesion tends to produce a stenosis or a regurgitation through the valves. As these lesions are met with in advanced life, at a time when the heart is not called upon to do as active work as in younger individuals, we often find no serious clinical signs connected with the pathologic changes, and if the sclerosis does not invade the line of closure of the valves the pathologic condition exists merely as an anatomic change, which gives rise to no signs or symptoms during life. Our decision as to the significance of the lesions must be made not on the discovery of a murmur, but on the condition of the heart muscle as to its size and as to its ability to properly carry on the circulation. Such lesions represent only an extension to the aortic valves of a localized sclerosis of the aorta.

A more important local condition in the heart is found in diseases of the coronary arteries. In this condition we find one of the most important and possibly the only cause of angina pectoris. It is in many cases the true explanation of indigestion and various symptoms of distress in the chest attributed by patients to some fault in the stomach. It is rather unusual in such cases not to find some changes in the radial artery which give strong evidence that our suspicion of disease of the vessels of the heart is correct. The heart is often not enlarged, but the failure of the heart is shown by intermittent action or irregularity, and substernal distress with shortness of breath on moderate exertion. Unless the heart muscle is secondarily diseased we do not find general œdema, pulmonary œdema and allied signs of heart failure.

Our prognosis in these cases must always be guarded.

Thirdly, the heart muscle may be seriously affected by localized disease of the arteries when the circulation is so impeded that the nutrition of the muscle suffers, and we find a gradual dilatation of the cavities dependent upon the weakened condition of the heart wall.

This form of heart trouble represents usually a different type from the enlarged heart due to a widespread capillary fibrosis. I have seen one case of rupture of the heart secondary to a closure of the artery, which had cut off the circulation in the wall of the left ventricle.

Among the most important symptoms of localized arteriosclerosis are the disturbances of the nervous system, central and peripheral.

Central. — Vertigo is a common and often a very annoying symptom in elderly people, due to an interference with the circulation in the brain; also tinnitus, for which we find no local cause or any disturbance of the ear. Often these are the only symptoms that a patient with marked sclerosis complains of.

Epileptiform seizures in old people represent a more extensive involvement; it is important to recognize such a cause for these attacks that we may not make a diagnosis of epilepsy and institute treatment for that disease. The anatomical distribution of the cerebral sclerosis may be in such a situation and lead to so marked a degeneration of the cerebral tissue that a progressive dementia gradually comes on.

Transient monoplegia and transient attacks of aphasia are frequently seen: the question arises whether the symptoms are due to small hemorrhages or emboli. In many cases the diagnosis is obscure, but the rapidity with which many cases recover seems to preclude the probability of such definite pathologic lesions. Further, frequent post-mortem examinations in cases under my care, in whom during life I had observed several attacks of paralysis of short duration, have failed to show any evidences of a preceding hemorrhage. But the cerebral vessels were markedly sclerotic.

The probability is that such symptoms are due to a spasm of the vessel walls, which temporarily impedes the circulation. The clinical name of vasomotor ataxia is not unsuitable if we bear in mind that it is only a name, and does not prove the exact pathologic condition.

Peripheral. — A very interesting class of cases similar in type to the cerebral cases just spoken of represents many forms of "rheumatism," especially muscular rheumatism. An old person with hardened arteries finds that after very moderate walking he has rheumatism in the legs; after a rest or a little rubbing of the part affected the pain passes. In the interval, when the parts are quiet, there is no pain and no local tenderness. Examination shows that the pain is situated in the muscles, and not in the joints.

Such cases are extremely common, and according to the grade of the arterial lesion, may be developed with or without exercise. The most extreme grade of the disturbance is found in the combination of symptoms so characteristic that they are honored with the name of intermittent claudication; in some cases the loss of function is so marked that there is in addition to the cramp-like pain in the legs actual paralysis. Where the blood supply of the nerves is especially affected we find symptoms of neuritis rather than muscular pain, as in the class of cases just described.

In spasm of the abdominal vessels we may find many cases of obscure disease of the abdomen. Such cases are apparently closely associated with the large class of visceral disease combined with local skin disease of the erythema type.

I have under my care at the present time a lady of advanced years who has arteries that feel like pipe stems. The heart is not enlarged. She has always on any exertion severe dizziness and vertigo. The examination of the eyes shows only a sclerotic condition of the vessels. She is subject at frequent intervals to attacks of severe abdominal pain. She has been under my care for many years. As her digestion is never good and she has not much flesh I have asked several men to see her in consultation, fearing that I might have overlooked some possible malignant trouble. No one has been able to correct my own opinion, that the whole trouble is due to a marked vessel change: this diagnosis has been practically confirmed by the occasional occurrence of small patches of subcutaneous hemorrhage, which follow what she speaks of as localized rheumatism.

In diffuse arteriosclerosis we find clinical symptoms of a different type from those just described as occurring in localized sclerosis. Pathologically, in this type calcareous degeneration is not common and the larger vessels, as the aorta, may not show changes in the vessel walls. The process consists essentially in a disease of all the smaller arteries of the body, shown especially by changes in the media. As I have already said, it is a disease most frequent in persons from forty to fifty years of age, and represents evidently not a process of degeneration, but a growth of the tissue of the vessels.

This is the type that is most suggestive of some toxic process due to infectious disease or some auto-intoxication secondary to over-eating, alcohol, or faulty digestive processes. Clinical observations point strongly to two important causes — excess of food and improper digestion.

The individuals are usually essentially robust and well nourished: pallor is a prominent symptom: the explanation of the pallor is not plain, but the blood examination shows the pallor is not due to a deficiency of hemoglobin, nor to a reduced number of red corpuscles. The theory has been suggested, and seems probable, that the color of the skin is due to spasm of the smaller vessels.

Two important organs are secondarily diseased — the heart and the kidneys.

In the heart we find the most important factor: in all cases the heart is more or less enlarged, and though there may not be much trouble while hypertrophy is the main factor, in later stages there is a secondary dilatation of the heart cavities. A very large number of cases of "heart disease" are primarily cases of arteriosclerosis with secondary disease of the heart.

Such cases are often first called to our attention by a sense of constriction in the chest, shortness of breath on moderate exertion, and attacks of an asthmatic character. The asthmatic attacks may follow any acute bronchial attack, or be the result simply of overexertion. The blood pressure is always high, — 160 or more, — the skin pale, and the pulse rapid, with an occasional intermission.

This is one of the chief causes of myocardial disease of the heart, as distinct from valvular disease. The presence or absence of murmurs is of no special significance as the dilatation of the cavities may be so great that a relative insufficiency may be found at any of the valvular orifices.

As the heart gradually fails we find increasing degrees of œdema, until the patient may die of general anasarca. We also find chronic passive congestion of the liver, spleen and kidneys, as in any case of heart disease, with broken compensation.

In cases in which the kidney is the chief organ affected we have the picture of the small contracted kidney. It was the association of arteriosclerosis and kidney disease that first led to investigation of arteriosclerosis in the work of Gull and Sutton.

In fact, cases of so-called "cardio-renal" disease, a name in frequent use some years ago, were cases of arteriosclerosis, in which the heart or the kidney was involved to a great or less degree.

Treatment. — In prevention, we cannot, unfortunately, escape all infectious diseases, but we can advise our patients to avoid excess in food, especially when no active exercise is taken, and to care for a proper elimination of excrementious matter.

When the disease is recognized at an early stage, before the heart is seriously involved, much can be gained for the patient by a careful regulation

of the diet. Excess of nitrogenous food, especially meats, should be avoided; further, the weight of the patient should be very carefully reduced by a reduction of the total caloric value of the food taken.

The work should be reduced, both physical and mental; a man with an early arteriosclerosis must learn to live on a lower plane.

One drug I consider of value as a preventive measure and, perhaps in some cases, as a curative measure, iodide of potash. This drug I usually order for three weeks in a month in a dose of five tenths gr., three times a day. When iodide of potash disagrees with the stomach, iodide of strontium may be substituted though it seems to me less efficacious.

Small doses of nitroglycerin give temporary relief to many of the symptoms and may do permanent good.

In most cases saline cathartics are indicated.

In recent years there has accumulated considerable evidence that permanent good is accomplished by the use of electricity in the form of the high frequency current.

DISCUSSION.

Dr. George G. Sears, of Boston: One of the most interesting clinical aspects of arteriosclerosis, but of which Dr. Jackson has not spoken in his able paper, is the increased frequency of its occurrence, about which all observers seem to agree. We are accustomed to speak with satisfaction of the greater expectation of life now compared with a hundred and even fifty years ago, but our satisfaction should be considerably chastened by the fact that this prolongation has occurred in the years of adolescence and the statistics of the life actuaries of to-day appear to show that a man of forty-five stands rather a less show of arriving at the age of sixty-five than he used to, and one of the great causes of this is arteriosclerosis. The causes of arteriosclerosis, so far as we know them, are so bound up with the social, moral and physical life of the individual that it seems impossible that we should do much in prevention, since few persons are willing to listen to advice so long as they feel perfectly well. Our chief hope would seem to lie in recognizing it sufficiently early to be able to arrest or at least to delay the disease. Special interest should therefore be taken in those clinical aspects which are manifested in its incipient stage. Diagnosis is comparatively easy after it has progressed for a certain length of time. While it is a general disease it tends to progress with greater rapidity in one or another region, so that the picture will vary according to the organ which bears the brunt of the attack. The symptoms presented are those due to failure or perversion of function of the affected organ, added to which in many cases are symptoms due to spasm of the vessels at fault which lead to such manifestations as angina pectoris, angina cruris, or intermittent amaurosis, in the latter of which one may even see the spasm of the vessel. Early diagnosis, however, is a different matter, since the changes from normal are at first slight and often misinterpreted. Yet there are certain suggestive symptoms which are quite characteristic, particularly as we look back over the histories of those patients whom we have been able to follow from the beginning of the process. The most marked, and perhaps the most frequent, is the apparently causeless, but progressive loss of health which may be shown by lack of vigor, low spirits, inability to sleep as well as formerly, disturbing noises in the head, and sick headache; symptoms which we are accustomed to associate with neurasthenia, if one may still be permitted to use that term. Neurasthenia coming after forty should be looked upon with considerable suspicion. Neurasthenia it may be, but back of it circulatory disturbances should be looked for which may have contributed to, if they have not been the cause of the condition. The same suspicion should be attached to certain cardiac disturbances which are not infrequent in the early stages, some intermittency or irregularity of action, possibly a feeling of discomfort about the heart or even pain, not enough to complain much of but sufficient to call the patient's attention to the fact that he has a heart. These are symptons which are associated with such toxic substances as tobacco, alcohol or coffee, and such a cardiac condition may be dependent on them alone, but it should be remembered such symptoms are more easily produced when the arteries are beginning already to degenerate. There are also certain urinary changes which are suggestive and which I suspect are due, in part at least, to the spasm of the vessels in the kidneys, analogous to that in the heart which produces the symptoms of angina. The amount of urine which is passed and the specific gravity of the individual specimen may vary greatly as a result. These changes may be noticeable from day to day, or even from hour to hour; possibly one may find occasionally a slight trace of albumen, perhaps also a few casts. Careful and prolonged study of the urine may be of decided help in reaching a diagnosis. On physical examination one finds if the blood pressure is raised, some accentuation of the second sound of the heart over the base. The accentuation is usually more marked on the aortic side, but the sound in the pulmonic area may be the louder, a fact which does not seem to be generally recognized. The first sound of the heart as hypertrophy progresses is prolonged and heavier, but hypertrophy itself, which may or may not occur in arteriosclerosis, is often difficult to make out and is on physical examination frequently overlooked. Efficient assistance in recognizing the initial stages of arteriosclerosis, when much can be accomplished by treatment, is furnished by the various instruments for estimating blood pressure, and their use as a supplement to the trained finger should never be omitted when the patients have reached middle life. Persistent high pressure is a potent cause of arteriosclerosis, but arteriosclerosis is not necessarily associated with high pressure. Clifford Allbutt's classification of the disease seems to me the best one from a clinical standpoint, but it does not seem necessary to except from this classification, as he does, some of its rarer forms. He divides it into three classes. First, involutionary, which is often hereditary, and whatever it may be due to it is not a result of high living. It is not necessarily associated with high pressure, indeed it often is not, and for that reason, Dr. Jackson says, apoplexy is comparatively rare in these cases, even when the arteries are greatly degenerated and calcareous. Such cases are more apt to die from gradual failure, unless cut off by intercurrent diseases. The second class is of mechanical origin and a result of continued high pressure. These are the cases in which the sphygmomanometer is most useful by giving timely warning. The third class is toxic or infectious. It occurs especially in comparative youth and may or may not be associated with a rise of blood pressure. Fortunately for our patients we are gradually approaching knowledge that high pressure is a symptom and compensatory. In the circumstances under which he is living it is necessary for the life and comfort of the individual and no more to be treated than a cardiac murmur. It is fortunate also that drugs are

powerless to reduce it, and the well-meant but misdirected efforts of the physician to reduce it are successfully resisted by nature, which in her efforts to preserve the life of the patient fails to honor his drafts. It should also be emphasized that high pressure and a strong myocardium are not necessarily associated, since a weak heart may be accompanied by a high tension pulse. This accounts for the beneficial action of digitalis in some cases, even when the tension is very high. The patient may require a pressure of 200 or more in order to live, and to overcome this resistance in front the heart requires the tonic effect of digitalis.

Dr. Richard Hogner, of Boston: Dr. Jackson is perfectly right in saying that we all have to expect arteriosclerosis sooner or later. It is not due to old age, however, but because we are using alcohol, tobacco, coffee, tea; are over-eating too often; also often over worried. Arteriosclerosis is a rare condition in animals, no matter how old.

The natives on the islands of Samoa and Fiji, living in the interior of the island, mostly on fruits and water (using no stimulants whatever), and a healthy, natural life, are strong, intelligent, tall, often over six feet, and at the age of sixty are almost as vigorous as one of our boys at twenty.

The same race, living at the coast, under the ban of so-called civilization, drinking alcoholics and using tobacco, are weak, dull, small, degenerates, and at the age of thirty are almost as weak as one of our race at sixty or more.

In California are living many Indian women at the age of one hundred to one hundred and thirty years. One at the age of one hundred and twenty carried on her back a bag, containing six big watermelons, for three miles.

A common symptom of arteriosclerosis is redness of the face, a symptom the most elderly persons show, often very markedly.

To repeat, I do not think that arteriosclerosis is caused by old age, but that the symptoms of wrong living do not show up before we are old.

Dr. William H. Robey, Jr., of Boston: There is one form of arteriosclerosis which has particularly interested us at the Boston City Hospital. I refer to the cases in which there is marked widening of the aorta to percussion, with pain and pulsation in this area. The differential diagnosis between arteriosclerosis and aneurism is not always easy in these patients. One patient was a man weighing 220 lb. with a thick chest making percussion unsatisfactory. He had paroxysms of pain under the sternum radiating to the left arm. He had an increased area of dulness, and the x-ray expert thought that he had an aneurism. Dr. F. C. Shattuck saw this patient in consultation, and considered the condition one of arteriosclerosis. Subsequent treatment proved this to be the correct view.

A second case has presented more difficulties. A stout woman of fifty-five has had substernal pain and pulsation for two years. Her blood pressure is 230. On sinking the finger into the suprasternal notch a distinct pulsation is felt synchronous with systole. Several members of the staff who have seen her with me have agreed that there was strong evidence of aneurism, but two x-ray examinations nearly a year apart have been against this condition. Under treatment for arteriosclerosis she has slowly improved.

Figures given out by the Russian Government Sanitary Commission recently show that since the outbreak of the cholera epidemic, about the middle of May, until the end of July, 37,652 cases occurred with 16,651 deaths. The entire region affected includes forty-two provinces and territories. In the week ending July 23, 13,374 cases were reported, with 5,979 deaths. — *Med. Record.*

MEDICAL INSPECTION IN PUBLIC SCHOOLS.*

BY JUSTICE G. HANSON, M.D., NORTHAMPTON, MASS.

Compulsory medical inspection in public schools in the United States was first enacted as a law in Massachusetts in 1906. Probably no health legislation of recent years has been so important, for it opens the way to a very general dissemination of knowledge as to conditions pertaining to health and disease, and can be made a tremendous factor along the lines of preventive medicine.

The law as it exists gives the school inspector control over all health matters pertaining to pupils, teachers, janitors and the sanitary conditions of school buildings. The law does not provide for any penalty to parents who neglect the health of their children. This must be a matter of education, but a penalty can be imposed under the Compulsory Education Act for absence from school by reason of defects that are within the power of the parent to correct, and under this act courts have imposed a fine for failure to keep the child free from pediculi and its ova, and for not treating impetigo contagiosa.

Dual powers have been granted certain school and health boards in the appointment of school physicians, but while these boards should co-operate, it would seem best that appointments be made by the school boards, for the reason that it is so essentially an institution within the school, and also because school boards are more stable and the office is not as liable to become a political football.

Short experience in the work led physicians to advocate a school nurse, one who could follow up the cases, go to the homes and interest the parents in the health of their children and get them to consult their family physicians. The doing of this naturally brought the nurse in contact with cases of destitution and has led to an alliance of this work with civic leagues, children's societies and charitable institutions. I believe a nurse to be of invaluable aid to the school inspector and and a most important factor in the scheme of school inspection.

As there is no provision for general supervision in the application of this work, we find throughout the state all sorts of school inspection, some medium, some fair, some worthless. In a few cities and towns regular visits, complete records and detailed reports are made. This last method is the only proper way of expending public funds, and the work, if made uniform throughout the state, would open up a store of knowledge as to the general health of children, the manner of handling epidemics, conditions in school houses, the care and distribution of books, pencils and paper, the effects of dust, heat and moisture, and the care of defectives.

To successfully accomplish this, there should be established a department of hygiene, having nominal control over school inspection and perhaps over the thirteen health inspectors who are carrying on a similar work in shops and factories.

* Read before The Massachusetts Medical Society, June 7, 1910.

Then by furnishing the inspectors with uniform blanks, and calling for certain facts, fairly even work would be obtained throughout the state, and slipshod methods would be eliminated.

In this work the teacher has the best opportunity of watching the child, and to her we must appeal for the best results of inspection. It would be well if normal schools would give teachers instruction in hygiene, and to so much of children's diseases and defects as they are likely to meet in their work. Every inspector should get his teachers together two or three times each year and instruct them in such conditions as may come to them, and during the year keep in touch by bulletins relative to individual schools.

The teacher being nearer to parents, should have occasional parents' meetings, and to them give advice as to proper food, clothing, sleeping quarters, personal care, etc. In one of our schools, attended largely by children of foreign parents, the teachers have had the children interpret this advice to parents, and much interest has been awakened, and the results have been cleaner children, more open windows in sleeping rooms, more baths, suitable food, more sunlight and more tidy homes.

It has been our endeavor to keep our schools open during epidemics and to prevent or check epidemics, because every closed school means a money loss to the city. A very interesting fact was developed relative to measles, showing the contagiousness of the disease even before the child is known to be ill. In a room of thirty-five children about seven years of age, a child was in school Friday apparently well. On Monday the child was ailing and kept at home. On Wednesday, a diagnosis of measles was made. On Thursday eighteen children in that room who never had the disease were excluded for two weeks and a note sent the parents that they had probably been exposed to measles. Within the two weeks sixteen of the eighteen were reported as ill with the disease. By getting these cases out early we were able to keep the school open and not another case developed in the building. By following this method we have been able to keep the schools open and check epidemics.

Examinations of our children have brought out four important facts:

First: The great number of children with defective teeth, or a better description might be with septic mouths. It is a remarkable fact that these children are found to have inflammatory diseases of the pharynx and nasal cavaties, and are often anemic. It surely must be ignorance which permits a parent to allow a child to lose its first molars as fast as they come and have them go through the most active development period of life without the teeth so essential to proper mastication.

Second: The large percentage of children with defective sight, 10% having only $\frac{1}{3}\frac{0}{0}$ vision or less. By law parents are notified, and it is by experience that a large proportion of these are attended by itinerant oculists and low grade opticians. Is it logical for a state to insist upon yearly examination and reports and then permit unskilled persons to treat such cases?

The medical profession should stand as a unit in demanding that no person should prescribe lenses or treat the eye who has not had a thorough medical training not only in eye defects, but in such other conditions of the human body as produce disturbances of vision.

Third: The great number with enlarged tonsils and adenoids. Most parents readily heed the advice of the family physician and have them removed.

Fourth: The number found anemic. These children are usually found in our schools among the foreign born and the more illiterate. Conditions prevailing to cause anemia and tuberculosis, lack of proper food, obstructions in the vault of the pharynx, small tenements and insufficient air and sunlight. Physicians have been impressed with the necessity of aiding these children, and experimentally open air schools have been established with most gratifying results. It is not an expensive thing to try, for all that is necessary is to construct a platform 35 ft. by 35 ft. on the southern exposure of a school building and put an awinng over it with flies on the three sides that can be used if the sun is too bright. On rainy or very cold days the children can occupy the adjoining schoolroom. Except for a few weeks in winter, this outdoor room can be used for anemic children with most gratifying results, being followed by a marked increase in the children's weight and in the percentage of hemoglobin in their blood.

This leads me to discuss a special school that should be established in every city, — a school for defectives. There are from 40 to 50 such to every 2,500 school children, and in our public schools they are a nuisance and a hindrance to the normal children who are thrown into contact with them, besides interfering with the work of the teacher and getting themselves no benefit from attendance. Segregrating these children and placing a trained instructor over them, they can be taught considerable that will not only render their care more easy to parents and guardians, but will help these unfortunates to lead a more useful life.

School work demands the co-operation of the medical profession! Its aim is to establish a closer relation between physicians and their families, to educate the public in matters pertaining to health and comfort, to check epidemics, to educate in relation to tuberculosis, and matters of home hygiene.

If careful systematic inspection is carried on throughout the state, succeeding generations because of it will be burdened by less physical and mental cripples, will be more free from contagious and infectious diseases, and will have a more intelligent conception of disease, and its cause and effect.

DISCUSSION.

Dr. Thomas F. Harrington, of Boston: The most important factor to-day in discussing medical inspection of schools is the recognition of the great responsi-

bility that the state, especially the state of Massachusetts, has placed upon the medical profession in the newer and wider conception of this branch of preventive medicine. In its law of compulsory medical examination of all public school children, as well as in its child labor law of 1910, this state gives to the detection of contagious diseases secondary consideration only, and points out clearly that such duties are by no means the principal functions of school physicians. This view is in accordance with the established facts of modern bacteriology, and is founded upon the experience taught by the past fifteen years of school inspection.

Besides the immunity afforded by compulsory vaccination, more than 80% of children entering school for the first time have had measles, and more than 45% have had scarlet fever. Tuberculosis in its transmissible form is exceedingly rare among the children; and few, if any, of the 1% "carriers" of the Klebs-Loeffler bacillus have the virulent form of the microbe present. Special hospitals for the care of contagious diseases, the free bacteriologic examinations of sore throats by cities and towns, and the free supply of antitoxin and vaccine sera by the state, have combined to remove more than 60% of these cases from homes and schools before they had become a menace to others. The supposed influence of school closure as a factor in the decreased morbidity of contagious diseases during the vacation period is now recognized as a coincidence in the seasonal fluctuation of those diseases, insomuch as the decrease in the number of cases begins two weeks before the closing of school in June, and the increase begins two or three weeks before the opening of the schools in September. This is especially significant on account of the well-recognized short period of incubation in these diseases of childhood. The extreme contagiousness of measles before the appearance of the rash, and the evidence to-day that the desquamation in scarlet fever is not the chief source of contagion in that disease, are both factors in preventive medicine, emphasizing the need of greater knowledge of contagion in the homes rather than an argument in favor of the daily inspection of schools by physicians. The rarity of school outbreaks, independent of general or neighborhood outbreaks of transmissable disease, is likewise significant.

While the congregation of children in large numbers daily should not be underestimated as a possible means of spreading contagion, nevertheless we are not warranted in charging them with being "foci" of contagion greater than other gatherings, public and private. Schools, on the contrary, offer the best common medium for the control of these diseases. Teachers and school nurses learn frequently from the children of the existence of contagion in the homes which otherwise would go unreported. This is especially true concerning measles and whooping cough, diseases lightly considered, in fact invited, by the laity on account of the supposed freedom from danger and the immunity afforded by an attack. The truth is that these two diseases are each more fatal than scarlet fever or typhoid fever, and each lays a foundation for tuberculosis not equalled by any other one cause. If the medical history of each child entering school for the first time could be made a part of his registration, much useless exclusion from school could be avoided and unnecessary exposure to prevailing neighborhood contagion averted. School principals are very ready to co-operate with medical authorities in all measures tending to maintain a high attendance of healthy children. Already they have taken the initiative in reducing to a minimum the possibilities of spreading infection by means of "contact" among the pupils while in school. The lessons in prevention will take time for their dissemination into the homes and among the public. In the meantime, school nurses are doing most valuable work in educating the homes, and the results in combating the spread of infectious diseases, thus far accomplished, promise much more than those guaranteed by the daily inspection of schools by physicians.

The eradication of the skin diseases and the parasitic affections communicable among children do not call for daily attendance of the physician. These are chronic affections usually and are remedied by close continued treatment only. This no medical inspector recognizes as his function; nevertheless, few parents ever seek private or public medical aid for these children. They are diseases calling for isolation, if not exclusion. To exclude these children without some "follow up" system for treatment aggravates the situation and manufactures truants, if not vagrants, in many cases. School nurses under medical supervision have been able to solve this problem in many localities, and the absenteeism of the infected pupils has been reduced to a minimum; protection to the other children in the home and in the school being assured.

When we pass fron the consideration of the infectious and the parasitic diseases into the wider domain of preventive medicine, we find abundant opportunities for the best thought and the highest service of the physician. A new field in medicine awaits him. Educational authorities and grade teachers recognize the shortcomings of the present system of medical inspection in aiding them in adjusting school life and physical growth so that each child shall receive his full complement of both. Many conscientious medical inspectors have done much to meet the requirements of the situation. Where medical inspectors have been health department physicians of the contagious disease division, their work in the schools has necessarily been incidental and, to a great degree, associated with the work of that division. Such a system fails to cover the larger part of the actual conditions in the schools needing medical attention. The health department and the school department should bear co-equally the solving of the problem awaiting solution. There need be no duplication of efforts, there should be no friction. Neither should the surgical aspects of some of the problems met in the inspection of large groups of children be so prominently emphasized. Statistics based upon the investigations carried out in the Boston schools could be quoted to prove that much of the sensational announcements relative to the importance of these factors in causing mental and physical retardation are unwarranted. A summary of the problems met in the schools shows this. These problems are varied; and although pedagogical in aim, nevertheless they are strictly medical in solving.

In the first place comes the detection, in the earliest years of school life, of those defects tending to prevent the child receiving the fullest benefits of his school work. Under this heading we find defects in speech, in vision, or in hearing, bad postures, lack of nervous stamina, inco-ordination, epilepsy, chorea, carious teeth, anemia, glandular enlargement (including tonsils and adenoids), improper feeding, insufficient sleep, overwork, etc. Then, too, the amount, the kind, and the time of the daily gymnastic exercises, of organized games, plays, recreations, and dances, — all means of mental as well as physical development when properly guided and controlled along physiologic, as well as psychologic, lines. The control of athletics so as to give to each pupil an opportunity to develop a healthy physique without the danger of surpassing the age, sex, or individual limitations of each one is greatly needed, a problem which can be solved rationally by medical guidance only. The physician is likewise an essential

factor in dealing rightly with the retarded pupil, with the mentally backward or defective, as well as in guiding the over-bright; also in fitting school programmes, so that the growth, development, fatigue, and rest shall each be harmonized; and in the kind and quality of school lunches, etc. Nor are the problems any less pressing in the sanitation domain. Here the medical advice of the specially trained physician is needed in the choice of school sites, in the planning and the arrangement of the buildings and grounds, as well as in pointing out the imperfections in those at present occupied and in the improvements necessary to render them sanitary. This includes also the establishment of open-air classes and the enforcement of rules concerning ventilation, heating, room temperature, lighting, seating, cleaning, as well as the supply of bathing and hygienic drinking facilities, — all problems of health greatly neglected to-day. Finally the great problem of interpreting rightly the advances made in hygiene and in physiology, especially in physiologic chemistry, so that those truths may be presented to the teachers and normal school pupils in such a way as to enable them to instil into the minds of the children an interest, as well as a useful knowledge of the laws of health. Hygiene and physiology as taught to-day in the schools are very far from fulfilling such needs, — a shortcoming recognised by most grade teachers and special teachers.

The problems and the opportunities awaiting the physician in school life to-day could be enumerated without limitations, embracing many of the most interesting branches of medical, psychological, and pedagogical aspects of child life. They are not diseases controllable by board of health laws. The aim and the purpose underlying all medical supervision in the schools are primarily that all grave hindrances to the school life of the child and to his doing successful school work shall be prevented and removed. This makes the physician's position on the school organization educational as well as medical; consequently the authority to whom the control and purpose of school work is especially entrusted should determine in a measure the duties and the qualifications of its medical officers; and this department, to which all the investigations and reports pertain directly, should control the services of those making such reports.

Medical inspection, medical supervision, school hygiene, or any other system for combining medicine and pedagogy, calls for an organization on the widest plan of preventive medicine. The public will hold the medical profession responsible for the type of the work done as well as for the immediate results. The work calls for a special line of instruction in medicine not yet offered in many medical colleges. The medical profession, however, cannot avoid the obligation nor neglect the responsibility. Modern medicine has made this an evident duty of the physician. State medical societies, such as this one, should act at once through its special committees by formulating a plan, by establishing the qualifications of fitness, as well as by fixing the rate of compensation of those who are to undertake this branch of medicine. This is essential for the guidance of the state and city officials, in order that this important branch of preventive medicine may be uniform and effective according to the particular needs of each city and town, and the whole scheme in perfect accord with the highest ideals in medicine as well as in education. With a school medical department established upon some such basis, the school physician would readily become the counsellor and guide whom school authorities are seeking, in order to give to school life that higher efficiency and greater health which the recent advances in medicine and in pedagogy have made possible.

THE DIAGNOSIS OF INFANTILE PARALYSIS IN THE PRODROMAL AND EARLY ACUTE STAGE AS FOUND IN THE EXPERIMENTAL STUDY OF ACUTE POLIOMYELITIS IN MONKEYS, WITH REPORT OF FINDINGS IN FOUR HUMAN CASES.*

BY WILLIAM PALMER LUCAS, M.D., BOSTON.

The past year has brought out so many interesting facts about the infectious nature of acute anterior poliomyelitis, its transmissibility, its epidemiology, and, recently, some valuable facts in experimental immunity, that now great efforts are being made to discover some means of protection. In view of such a discovery, and having failed thus far to find the specific etiological cause, it seems of some import to find some means of making a fairly accurate diagnosis early in the disease, as there is little or no hope of being able to check the process after paralysis has appeared. The invasion of the white matter of the cord is undoubtedly an end result of the acute process, so that when the paralysis is first observed the virus has already about spent itself. This being so, there must be some indication in almost every case that the virus is at work some time before the paralysis appears.

The New York investigation of the prodromal symptoms agrees completely with the early symptoms found in animal experimentation. The most noteworthy signs are those of change of disposition. At times slight, but fairly constant and characteristic, is the restlessness and irritability that often appears several days before any other symptoms. Or the other extreme of apathy may be moderately marked for a number of days before one is aware that the paralysis is present. In these cases the occurrence of paralysis is much harder to determine, or, at least, we are not so apt to notice it as early as in the irritative cases. The paralysis may even be ushered in with delirium and convulsions or epileptiform attacks, which may last for several days before the paralysis is noted. In the exceedingly irritative cases the diagnosis of epidemic meningitis is most often made. And, indeed, it is really a distinct type of acute meningitic anterior poliomyelitis. Experimentally, it is hard to be sure of pain, but pain in the prodromal stage is by no means an uncommon finding, most often in the back along the spine, or in the joints of the extremities, which may show swelling and tenderness. Headache, general or frontal, is not infrequently met with in children old enough to locate the pain, and this is often accompanied with rigidity of the neck. If with any of these nervous manifestations there should be any trouble in the upper air passages, as coryza, bronchitis or sore throat, suspicion should at once be aroused. In all of our animals, and in each of our four human cases, there was some affection of the upper air passages along with one or more of the above nervous manifestations. Temperature though present in

* Work done under a grant from the Proctor Fund in the Department of Surgical Research and Serum Diagnosis, Harvard Medical School. Read before The Massachusetts Medical Society, June 8, 1910.

nearly every case is not typical and is of little use as a guide. It is usually of short duration, two or three days, though a low temperature of about 100° may continue for a week or more, as may be seen, in our four cases, in three of which it persisted for over three weeks. The bowels show no particular change in the majority of cases, though either constipation or a moderate diarrhea may exist.

These clinical manifestations in conjunction with certain definite laboratory findings which I have been able to show in an experimental study, and in a few human cases that I had the good fortune to see about the same time, make the diagnosis somewhat more certain, though, of course, not as exact as some specific reaction by which we had hoped to be able to make a positive diagnosis, but in which so far we have failed. Yet this combined information should be of great assistance toward making a more accurate and early diagnosis in this condition.

POINTS OF DIAGNOSIS FROM SPINAL FLUID AND BLOOD IN THE PRODROMAL AND ACUTE STATE OF ANTERIOR POLIOMYELITIS FROM EXPERIMENTAL AND HUMAN STUDY.

The original material for experimental work was obtained through the kindness of Dr. Flexner, who furnished us with two different strains of virus. We were able to produce paralysis in three monkeys from this original virus, and were able to transfer paralysis through two subsequent series of inoculations. The work of diagnosis may be divided into two parts as we carried them out. First, the ordinary laboratory methods of blood and spinal fluid examination, and, secondly, the more complicated biological tests of these same fluids. All these tests were made before the inoculation in a large enough number to give us a fair idea of what normal findings were. These same tests were carried on during the period of incubation, through the prodromal stage and through the acute stage until the fluids examined returned apparently to their normal findings. The temperature findings were not constant except that in the first irritative stage there was a fairly uniform rise, with a drop to normal, often subnormal, during the acute stage, with at times a furthur rise toward the end of the acute stage or beginning of convalescence.

The study of the blood brought out at least two very interesting facts, and, when taken in conjunction with certain findings in the spinal fluid, will certainly make a strong diagnostic point early in the disease. The normal differential count ran about: Polynuclears, 60%; large and small mononuclears, 25%; lymphocytes, 12%; eosinophiles, 3%. In the acute stage there was a moderate to a constant lymphocytosis, the count being: Polynuclears, 40%; large mononuclears, 15%; lymphocytes, 40%; eosinophiles, 5%. Parallel with this lymphocytosis there was a marked and constant leukopenia. This drop in the white count lasted fairly consistently with the acute stage, disappearing about the time that the hyperesthesia or other manifestations of the acute stage disappeared. The average normal count of our monkeys was in the neighborhood of 20,000 per cubic millimeter. This count did not change during the incubation period, but did change occasionally during the irritative or prodromal stage, when there was a marked or moderate drop in the white count. During the acute stage there was always a marked drop, the lowest count being 8,000 on the second day after paralysis was first noted.

SPINAL FLUID.

The spinal fluid shows even more marked and very characteristic constant findings during the incubation period, prodromal and acute stage, disappearing about the time that the acute symptoms begin to subside, being at its height either in the prodromal stage or on the first or second day of the acute stage. Before inoculation it is often impossible to get even one drop of spinal fluid from a lumbar puncture; most of our attempts gave nothing more than dry taps. However, when successful, there were only one or two cells to be seen in an ordinary Thoma-Zeiss counting chamber, and on staining these were apparently large mononuclears or plasma cells. During the incubation period there is a marked increase in the amount of fluid that may be obtained from lumbar puncture, and the cells in the fluid are very markedly and characteristically increased anywhere from 100 to 300 cells per cubic millimeter. These cells are mainly of the large mononuclear type, with some polynuclear cells and lymphocytes. In the prodromal stage there is even a more marked increase in the cells, often reaching 1,000 per cubic millimeter. In this stage, also, polynuclears are still present, in some cases as high as 60%, though the large mononuclears and lymphocytes were very evident. In the early acute stage the increase in cells is very marked. The cells are now, however, mostly of the lymphocytic or very early form of cells, and sometimes very hard to place, as they are apparently undifferentiated cells. As the cells decrease in number, the polynuclears begin to return, and at the end of a week or ten days there are very few cells present, mostly large mononuclears with a few polynuclears. In the prodromal and acute stage there was at times a fibrin clot. This clot would disappear fairly early during the acute stage. Fluid in our monkeys was never under any great pressure, though the amount was sometimes increased so that 5 ccm. was easily withdrawn. This occurred fairly regularly in the meningeal type of the infection.

A comparison of these experimental findings with the findings in four cases of acute poliomyelitis in children is of considerable value. These four cases were seen first between the second and fifth day of the acute onset. When seen all of them were running a slight temperature and were still in the hypersensitive state, with paralysis just commencing, so that the first findings in these cases are comparable with our findings in the early acute stage of our experimental studies. It will be seen from the chart that the blood find-

ings show from a moderate to a quite marked drop in the white blood count, with a lymphocytosis moderately marked in all but one of the cases, which was the one examined at the latest day. The spinal fluid findings are very interesting in all these cases, from the fact that in two of them definite fibrin formation was present early, which disappeared rapidly in one and very slowly in the other. The increase in cells was marked in all at the first puncture, and in three of the cases increased slightly later on in the course of the acute stage. The increase of cells was still present in two cases as late as the twentieth day of the acute onset. The type of cells found was practically parallel with the findings of the experimental spinal fluids, the lymphocytes and small mononuclears predominating on the first examinations, later being replaced by large mononuclears, and in the last findings polynuclears were beginning to reappear.

TABLE 1.

Noteworthy Prodromal Symptoms.

1. Irritability.
2. Restlessness.
3. Pain in spine or extremities.
4. Apathy.

TABLE 2.

Important Symptoms during Acute Stage.

1. Fever, 100° to 106°. Duration of fever, two to seven days.
2. Vomiting (25% in New York series).
3. Restlessness.
4. Apathy.
5. Rigidity of neck.
6. Headache (frontal).
7. Delirium.
8. Stupor.
9. Convulsions.
10. Photophobia.
11. Dysphagia.
12. Sluggish pupils.
13. General pain (early in 58%).
14. Absence of deep reflexes.
15. Cold extremities (vasomotor changes).

TABLE 3.

Types of Acute Poliomyelitis (Wickman).

1. Spinal poliomyelitic form. Sudden onset followed by paralysis.
2. The ascending form (Landry's paralysis). Involvement of respiratory centers. Most fatal cases belong to this type.
3. The bulbar or pontine form. Nerves most often involved: Facial, ocular, hypoglossal. May exist alone or with paralysis of extremities.
4. Encephalitic or cerebral form. May exist alone or with spinal involvement.
5. The ataxic form. Much like Friedrich's ataxia.
6. Polyneuritic form.
7. Meningitic form.
8. Abortive form: (1) General infection. (2) Symptoms of meningeal irritation. (3) Cases of much pain like influenza. (4) Cases with marked digestive disturbances.

TABLE 4.

Intracranial Injections Producing Acute Poliomyelitis in Monkeys.

Monkey No.	Material used.	Incubation.	Prodromal symptoms during	Acute onset on	Died on	Type of disease.
1	Virus K. (Flexner-Lewis) 4 ccm.	7 days.	5 days (2 days well.)	12th day.	17th day chloroformed.	Marked prodromata, spinal poliomyelitic form.
5	Emulsion cord (monkey) 12 ccm.	2 days.	1 day.	4th day.	6th day.	Bulbar, pontine type; respiratory paralysis.
7	Emulsion cord No. 273 (Flexner-Lewis) 2 ccm.	5 days.	1 day.	7th day.	12th day.	Spinal poliomyelitic form.
9	Virus M. A. (Flexner-Lewis) 6 ccm.	12 days.	2 days.	15th day.	40th day.	Spinal poliomyelitic form.
12	Emulsion No. 273 (Flexner-Lewis) 2 ccm.	4 days.	1 day.	6th day.	8th day.	Spinal poliomyelitic form.
15	Emulsion cord (monkey) No. 5, 2 ccm.	7 days.	2 days.	10th day.	10th day.	Meningitic form.

Average, 6⅛ days.

TABLE 5.

Spinal Fluid in Acute Poliomyelitis (Monkeys).

	Normal.	During incubation.	Prodromal.	Acute stage.
1	2 cells seen: 1 large mononuclear; 1 small (?) plasma cell.	6th day, 100 cells per cmm. Large mononuclears, 40%; small (lymphocytes), 60%.	10th day, 240 cells per cmm. Large and small mononuclears, 60% lymphocytes, 40%	14th day, 400 cells per cmm., mostly lymphocytes. 16th day, 60 cells per cmm. Lymphocytes. A few polynuclears.
5	Dry tap.		3d day, 1,000 cells per cmm. Polynuclears, 60%; mononuclears, 40%.	4th day, 800 cells per cmm. 5th day, 1,000 cells per cmm. Lymphocytes and polynuclears. Young cells undifferentiated.
7	No cells seen.		6th day, 160 cells per cmm. Excess of large mononuclears.	7th day, 12 cells per cmm. Lymphocytes. 8th day, 90 cells per cmm. Lymphocytes. 12th day, 20 cells per cmm. Large mononuclears. A few polynuclears.
9	One (?) plasma cell.		14th day, 120 cells to ccm. Lymphocytes, 40%; large mononuclears, 60%.	16th day, 200 cells per cmm. All lymphocytes or small mononuclears (young cells).
12	Dry tap.			7th day, 80 cells to cmm. Lymphocytes ++.
15	A few large cells and 1 (?) plasma cell.	6th day, 300 cells to cmm. Large mononuclears, 60%.	9th day, 150 cells to cmm. Large mononuclears, 30%; lymphocytes, 60%; polynuclears, 10%.	10th day, 180 cells per cmm. Lymphocytes ++. 30th day, few polynuclears found.

TABLE 6.

Blood (White Blood Count) in Acute Poliomyelitis (Monkeys).

A PROPHECY.

BASED UPON STUDIES IN PASTEURIZATION.

BY M. J. ROSENAU,

Professor of Preventive Medicine and Hygiene, Harvard Medical School.

Any study approaches the rank of an exact science in proportion to the precision with which it can explain and foretell the phenomena with which it deals. The mathematician would not admit the sanitary science into his classification of an exact science, yet our knowledge has reached a stage which enables the sanitarian to explain the causes and modes of transmission of many infections and therefore, to foretell and control the progress of epidemic diseases. Studies in epidemiology occasionally enable us to prophesy the course of events in the communicable diseases. Last winter Levy and Foster, health officers of Richmond, Va., sucessfully foretold and warned against an impending epidemic of measles. Over 2,200 cases occurred with 26 deaths. It is much easier to prophesy good than evil. It needs no seer to foretell that great sanitary reforms will be followed by diminished morbidity and mortality. Omens

of good sometimes fail on account of a lack of knowledge of the fundamental facts. This was the case in Washington after the installation of an expensive slow-sand-filtration plant for the purpose of purifying the Potomac River water. It was prophesied and generally expected that the purification of the river water would be followed immediately by a marked decrease in the amount of typhoid fever in the capital city, where typhoid had prevailed excessively since the vital statistics have been recorded. We now know that the failure of the purified water to make an impress upon the typhoid situation in Washington was due to the fact that very little of the typhoid fever in Washington was water-borne; most of it came through "contacts," and from milk.

A sanitary reform of no small significance has recently taken place in Boston which invites the hazard of a prophecy. In the fall of 1909 it was estimated that about 25 to 35% of the common market milk supplied the city of Boston was pasteurized. During the winter this process was extended, until now over 90% of the market milk furnished the city is pasteurized. Of the three large contractors who furnish over 90% of the city's supply, one of them pasteurizes all the milk he handles, and the other two pasteurize all excepting that which is "certified" or "inspected." The proportion of certified and inspected milk is much less than 1% of the general supply. This wholesale pasteurization is not under official surveillance (as it should be), but taking it for granted that it will be consistently and efficiently carried out, it must have a favorable impress upon the morbidity and mortality statistics of the city. It is easy to prophesy that there will be no more large milk-borne outbreaks of scarlet fever, typhoid fever or diphtheria such as those which Boston has suffered from severely during the past years. Occasionally scattered cases caused by infected milk may still occur through the contamination of a single bottle or can, but the steady flow of infection in the milk-stream from the farm to the city will be checked. In our studies in Washington we found that at least 10% of all cases of typhoid fever came from the milk. Kayser, in Strasburg, estimates that 26.7% of the typhoid fever occurring in that German city is due to typhoid bacilli in the milk. Just what percentage of the typhoid in Boston has its source in the milk is not known, but it is safe to prophesy that the wholesale pasteurization of the city's milk supply should cause a definite reduction of the typhoid fever in Boston. Glasgow, in 1903, began the practice of pasteurization of much of the milk sold in the public shops, and this in a great measure was thought to account for the reduction of typhoid fever from 20 to 30 per 100,000 to 10. In 1901 depots for the sale of sterilized and modified milk were established in Liverpool, and a study of the typhoid statistics of that city shows that the decrease in death-rate began after 1902. A somewhat similar coincidence occurred in London.

In the studies made in Washington it was found that there was much less typhoid fever among the customers of those milk dealers who pasteurized their milk and sterilized their bottles than among those who did not do so. For example, in 1906 there was only one dealer who sterilized all his milk bottles and pasteurized all of his milk, and it was noticed that of the large dealers he had the smallest number of typhoid fever cases among his customers in proportion to the milk sold; that is, he had 6.7 cases of typhoid fever from 100,000 gallons of milk sold, whereas, the ratio among others ranged from 16.6 to 113.9. That this was not a coincidence was shown by similar figures in 1907 and again in 1908.

Boston now has a safe water supply and with a safe milk supply it only remains to fight typhoid from the standpoint of a contagious disease, as is now being done in Chicago.

If much of the infant morbidity and mortality comes through the large numbers of active bacteria in the milk, we should also see a diminution of summer complaints and a saving of babies' lives. There are so many factors which enter into the problem with the babies that prophecy here is uncertain, but good effects may be anticipated and the results will be watched with keen interest.

The pasteurization of the great bulk of Boston's milk supply may be regarded as an experiment on a large scale, and its effects upon the vital statistics will be closely studied by sanitarians. It is a matter of regret that the temperature and time of heating the milk, the cooling and after-care, the sterilization of bottles, cans and containers, are not under the legal control of the health officials. The pasteurization of the general milk supply is too important a public health measure to leave to individual caprice. Assuredly "a pure milk is better than a purified milk." Pasteurization should be regarded only as a temporary expedient; it cannot atone for filth. Before the city of Boston can have a satisfactory milk supply it must institute measures that strike the source of the trouble; these consist in education and inspection. Through a centralized system of inspection and licensure a safer, cleaner and fresher milk supply can be obtained.

NOTES ON THE CONDITION DENOMINATED EXTERNAL AND INTERNAL ATONY, SUGGESTING ITS ASSOCIATION WITH TUBERCULOSIS.*

BY A. MACKENZIE FORBES, M.D.,

Surgeon to the Children's Memorial Hospital, Montreal, and Surgeon-in-Charge of the Orthopædic Out-Door Montreal General Hospital.

THE question of balance has at all times interested those who practise orthopedic surgery. The position of the center of gravity of the human being, when in the erect posture, is of importance.

Reynolds and Lovett, of Boston, have devoted a great deal of time to studying the position of the center of gravity or, as Cooke, of Hartford, would express it, the "question of balance," and their experiments and observations are of great interest to the medical profession at large

* Read at the Montreal Medico-Chirurgical Society, May 27, 1910.

One of the affections coincident with a change in the position of the center of gravity, an affection which causes more unrest than almost any other of these so-called minor complaints, is that of ordinary round shoulders, or stoop.

I am inclined to view stoop as being a manifestation of a laxity of the ligaments and a weakness in which the dorsal spine becomes kyphotic in shape, and the lumbar spine compensates by assuming the position of lordosis. It is, in fact, my firm belief that it is impossible to get a dorsal kyphosis without a lumbar lordosis.

Illustration of the apron or abdominal support used in conjunction with a corset or brace in the treatment of internal and external atony.

How to cure stoop or round shoulders has baffled most surgeons, all brace makers and nearly every mother. The British drill sergeant seems to have solved in a crude way the problem. His constant advice, nay, his every command to the recruit, is to hold his belly in and to raise his eyes but slightly above their normal position.

I believe that the way to cure stoop is not to attack the shoulders, is not to attack directly the kyphosis, but rather to attack it indirectly by preventing lumbar lordosis, and thus forcing a reduction of dorsal kyphosis, thereby changing the center of gravity.

It is only a question of balance. Throwing the shoulders back tends to broaden them; holding one's head back does not do away with a dorsal kyphosis, but, as soon as you straighten out the lumbar lordosis you are bound to have a compensatory change in the dorsal column.

My practice, then, is to get pressure at the anterior abdominal wall in the hope of primarily altering the lumbar curve, and, secondly, through altering the center of gravity, causing a reduction of the dorsal kyphosis or stoop.

To do this I make a light spinal brace which is somewhat similar to the spinal brace of the late Fayette Taylor. This brace has shoulders and a pelvic band. The shoulder straps are not to hold the shoulders back, but, with the pelvic band, are calculated to form two fixed points of counter pressure at the upper part of the dorsal spine and at the pelvis. This brace, as now described, can be expected to do little or nothing towards curing stoop. It acts simply as a vehicle to carry what I think is the important part of the whole appliance, namely, an abdominal apron or support, which is buckled to it and which can be expected to so control the abdomen of the patient that a lumbar lordosis is straightened out, which straghtening is followed by compensatory changes in the dorsal region of the spine.

I have been convinced of the truth of my theory for many years, and I have been treating my cases of stoop in the way suggested. I present to-night a little girl, M. H., for whom I prescribed such a brace as I have now described, on the 7th of September last.

As I have interested myself in this condition, and as I have been impressed with the compensatory lordosis which accompanies the dorsal kyphosis, I have seen that in many of these cases the lordosis is accompanied by a protuberant abdomen.

What is the cause of a protuberant abdomen? Ordinarily speaking, we are told that it is due to the patient's having an increase of adipose tissue.

I have not felt this to be so. How can it be explained that a person, whose arms and legs and every part are thin, and lack adipose tissue, should have a protuberant abdomen, if this protuberance is due to an increase of this form of tissue? Why should a person lay on fat in one place and not in any other? The possibility of doing this does not seem rational.

In looking for an explanation of this fact I concluded that probably a protuberant abdomen is due to a laxity of the mesentery, allowing a sagging of the intestinal tract. This is as far as I got.

Goldthwait,[1] of Boston, at the same time had been thinking. He got further. Goldthwait has been able to prove that many of these cases with stooped shoulders and a protuberant abdomen are suffering from enteroptosis, or, as he expresses it, ptosis. Goldthwait proved this first, and I think I am prepared to follow in his footsteps and prove it to you to-night.

He had a series of x-rays taken of patients to

[1] Joel Goldthwait, M.D.: Am. Jour. Orthop. Surg., April, 1910.

whom he had first given a bismuth meal. These photographs showed the stomach in many of the cases to have sunk beneath the umbilicus and even into the pelvis. The transverse colon even had assumed a somewhat similar position.

I believe that his procedure is this; in any case, this is the procedure which I have followed. The patient is given 1 to 2 oz. of bismuthcarbonate, emulsified and administered in milk. The patient is then given a couple of slices of bread and butter. The patient, after being encouraged to move about for a while, has an x-ray taken. The x-ray is taken from behind, namely, the x-ray tube is placed behind the patient's spine and the plate is placed in front of the patient's abdomen.

X-rays taken thus have demonstrated to Goldthwait's satisfaction that in many patients ptosis exists and that this ptosis acts definitely to the detriment of them.

Goldthwait has recently suggested that this condition of ptosis is a cause for certain of the chronic arthritides. He says "that under normal conditions food flows practically by gravity from the stomach into the first portion of the doudenum, which has no mesentery. In the second portion the ducts from the gall bladder and the pancreas open, and with a sagged stomach tending to shut off the outlet of the duodenum, and by pressure to interfere with the normal action of the pancreas, which lies in this region, it seems that there must be some interference with the normal secretion of the pancreas, therefore, with the early intestinal digestion.

"He makes the statement also that the lower border of the stomach in the normal subject seems to be about one inch or more above the level of the umbilicus and that in every case of this condition, so far studied by him, there has been a ptosis of this organ, which has varied from two to four or more inches below the umbilicus.

"He says that it was a natural inference that in poly-articular diseases, many of which are associated with various so-called digestive disturbances, an explanation of these symptoms might be found in the above-mentioned phenomena, and that what, for lack of a more scientific explanation, clinicians are in the habit of describing as disturbances in metabolism, might be no more or less than interference with chemical or bacterial reactions incident to the processes of indigestion when carried on under adverse anatomical conditions. Further support has been given to this supposition by a recent article of Maury,[2] who has approached the subject from a different point of view, in which, among other things, he has demonstrated that even the jejunum, which is ordinarily free from bacterial life, may be inhabited by some of those organisms which ordinarily reside in the large intestine and the ileum only."

I have not made any observations on any form of arthritis being associated with enteroptosis, but I do think that it is one of the things the possibility of which we should bear in mind.

[2] Jour. Am. Med. Asso., Jan. 1, 1910.

Goldthwait, however, has made the following statement, the truth of which I desire to prove to you to-night: "The common type of this condition, seen in childhood as well as in the adult, in which the shoulders are rounded, the lower dorsal and lumbar spines are straight, the lower abdomen protuberant and the neck and head thrust forward, have shown in the x-ray a marked sagging of the stomach and colon."

I have tried to present to you three patients. The first, M. H., was referred to my clinic last August by Dr. Patch because she had round shoulders.

The note taken on that date says that she had been treated for three years for her lungs at the tuberculosis dispensary.

Illustration of a simple brace which shows only the principle used in the support of the abdominal organs in external and internal atony. A corset with an apron or abdominal support is often used instead.

The second patient, S. K., was sent to me by Dr. Albert Nicholls because of pain in the region of the sacro-iliac joint. She has suggestions of a tuberculous pulmonary lesion.

The third patient, R. G., was kindly referred to me by Dr. Campbell Howard. She has a suggested tuberculous pulmonary lesion. Dr. Howard's house surgeon, in examining her, noticed a prominence of the vertebræ in the dorso-lumbar region, and asked Dr. Howard's permission to refer her to me for examination of the spine.

The first thing that I would like to draw your attention to is the fact that each of these three patients stands with a dorso-lumbar kypho-lordosis; each of them has a protuberant abdomen; each of them is in a more or less asthenic condition; each of them suffers from a suggested tuberculous lesion, and I may add that each of them was referred to me because of pain or deformity in or of the spine.

Each of these cases has been treated, and treated with some benefit, by elevating the stomach and by controlling the lordosis and, through it, the kyphosis by the simple brace demonstrated to-night.

The inference that ptosis is often conicident with a tuberculous lesion is not a new one.

As I have said already, I do not know how strongly Goldthwait's views regarding ptosis as a cause of arthritis will be borne out.

I do know, however, that many of the pains and aches which are ordinarily attributed to the spine and the sacro-iliac joint have not their source in either of these positions, but, rather, are symptomatic of a general condition in which there is a great laxity of the spinal and other ligaments associated with enteroptosis.

This condition I first called internal atony and enteroptosis, but more recently, I have been distinguishing it by the name of external and internal atony.

There are several interesting points about this condition: —

(1) As I have said before, its association with tuberculosis is of interest. I look upon it as curious that my three cases should have been associated with tuberculous lesions and convincing that it has often been noted before that such association is common. The question that this brings to my mind is, however, whether it is not possible that ptosis may be the cause of the gastric symptoms so frequently the first manifestation of pulmonary tubercle.

In the past we have been in the habit of attributing those symptoms to a toxemia. May I suggest the possibility of some of them being due to ptosis accompanied by a dilatation of the stomach.

(2) It is undoubtedly the cause of pains, both definite and indefinite, referred to the back, to the back of the thighs, and, I believe, in some cases, to the groins and front of the thighs.

(3) I believe that it is sometimes accompanied by spasm of the erectores. This spasm may be directly due to an accompanying tuberculosis of the lumbar glands.

(4) There is often a prominence of the dorso-lumbar vertebræ, (as in Dr. Howard's case), which prominence would suggest Pott's disease of the spine.

(5) A dorso-lumbar kypho-lordosis is common, this condition varying from an "s" shaped curve to a curved upper dorsal and straight anterior slanting dorso-lumbar spine.

(6) There is probably always a more or less protuberant abdomen.

(7) There is possibly a slight rise in temperature especially of evening temperature.

(8) It is often associated with a neurosis.

This condition should be distinguished from,

(1) Pott's disease of the spine. I have no doubt that the difficulty of the diagnosis between these and early cases of Pott's disease will be found to be great. Of course, there would be no difficulty in the cases of fixed deformities of the spine, but the time to make a diagnosis is not when deformity has resulted, but in the early stages of Pott's disease.

(2) Sacro-iliac disease. I think that beyond doubt, a great many cases of sacro-iliac pains which have in the past been diagnosed as due to affections of the joints were really more than this; that the sacro-iliac pains were really a manifestation of a general condition and not of a localized lesion in these sacro-iliac joints.

(3) The so-called rheumatoid conditions. These affections will also have to be excluded. As I have said already, Goldthwait has suggested that they, or some of them, may be caused by it.

(4) Tuberculous lumbar glands. Recently we have been attempting to diagnose this condition, and in a recent paper I have suggested that they may be a precursor of Pott's disease. My position tends now rather to assume that tuberculous lumbar glands in many cases accompany this more general condition that I have called external and internal atony.

Medical Progress.

RECENT PROGRESS IN LARYNGOLOGY.

BY A. COOLIDGE, JR., M.D.,
AND
D. CROSBY GREENE, JR., M.D.

THE SPHENO-PALATINE GANGLION.

Sluder's recent publications on the anatomical and clinical relations of Meckel's ganglion to the nose [1] have aroused interest in the whole subject of neuroses of nasal origin, and suggest fertile fields for future investigations. He calls attention to the anatomical fact that the ganglion lies in the pterygo-palatine fossa close to the spheno-palatine foramen. It, therefore, is very close to the external bony wall of the nose, in which the spheno-palatine foramen occurs as a small deficiency at its upper superior part. The foramen seems to be accurately placed at a point just posterior to and immediately above the posterior tip of the middle turbinate. The ganglion lies close to the plane of this foramen. Meckel's ganglion is, in fact, in quite as close relation to the nose and its accessory sinuses as is the optic nerve. It is, therefore, reasonable to assume that inflammatory processes pass over to Meckel's ganglion. According to the author's observations, characteristic disturbances have followed post-ethmoidal and sphenoidal suppurative inflammation which cannot be explained otherwise than by assuming that Meckel's ganglion has become involved by extension. In other cases the conviction has been equally positive that the extension has been from the nose proper.

The typical picture of these neuralgic phenomena is of pain which begins at the root of the nose, extends downward over the maxilla and backward on the mastoid, to become severest posterior to its tip; thence extending backward to take in the entire occiput, and downward into the neck, shoulder blade, shoulder and sometimes into the axilla. This pain very rarely invades the upper part of the head.

Remembering the position of Meckel's ganglion, in close proximity to the sinuses and the widespread distribution of its branches and connections, he felt that the distribution of pain was possibly due to inflammation extending to or acting upon the ganglion and that cocaine applied over the spheno-palatine foramen might probably prove effective in at least mitigating the pain. The experiment was tried and succeeded even beyond expectation. During an attack an application of a single drop of dilute solution 4% cocaine, through the nose to the region overlying the ganglion, was followed by only the faintest relief, but with a drop of saturated solution the relief would usually become complete. The author also puts alcohol in direct contact with the ganglion. A straight needle directed upward and outward under the posterior fourth of the middle turbinate will reach the spheno-palatine fossa, just where the ganglion lies. The injection of the alcohol aggravates the characteristic pain already described but the exacerbation is transitory and is followed by relief. In one of the cases reported, applications of ½% formaldehyde were continued over a period of four months, the pain behind the eye and in the jaw having stopped at the end of four weeks, for the most part. It occasionally returned in a lesser degree. The intervals between the "bad spells" became longer, and their severity lessened. The author calls especial attention to a case of acute access of glaucoma. In this case the area of the spheno-palatine foramen was inflamed. One application of 50% cocaine to the spheno-palatine foramen stopped the violent pain. It did not return. The attack aborted. In this case the other eye had been lost by glaucoma three years previously. The pain had been relieved only by iridectomy. But despite this, there had lingered always a little pain in this eye. An injection of alcohol into Meckel's ganglion aroused this pain to great severity, which lasted about three hours and then began to subside, requiring a week to stop all together. But when the reaction was finally over the old pain had stopped.

In a later paper [2] he describes two cases of typical spheno-palatine neuralgia in which he notices an asymmetry of the arches of the soft palate, with a deviation of the median raphe towards the well side and a diminution of tactile sense on the affected side of the soft palate and nostril.

NASAL ASTHMA.

A short paper on the relation between asthma and the nasal cavities is published by Nikitin. [3] Asthma is due to a contraction of the bronchial muscles through the vagus, aroused by peripheral irritation, often in the nose. The irritable zone is the upper and middle turbinate and the superior and middle meatus. This region is supplied by nerves from the spheno-palatine ganglion, and it is through this that the reflex disturbance is distributed. Surgical and other local therapeutics in this region sometimes produce an effect on the asthma, sometimes they do not. The majority of authors are in favor of local applications and opposed to surgical methods. The author believes that swelling of the mucous membrane of the sensitive area may be the peripheral source of asthma, perhaps by squeezing the nerves in the mucous membrane. Some other factors, heredity, increased irritability of nerves generally or locally, are also probable. The author's treatment, in addititon to internal medication and hot baths, consists in a thorough douche of salt solution morning and evening.

ATROPHIC RHINITIS.

From the study of many children with especial reference to the first symptoms of ozena, Baumgarten [4] describes an early stage in which the lower turbinate becomes temporarily engorged, generally unilaterally, with a tendency to form scabs. This engorgement gradually diminishes in frequency and extent until the lower turbinates remain shrunken and the stage of crust formation begins. The first symptoms he discovered by careful search in younger and younger children until he concluded that the disease may be present at birth, but symptoms rarely appear before four years of age. The author does not believe that it can be contagious on account of the very large number of cases in which with every opportunity for infection, the child remains well. It appears sometimes to be inherited, especially from mother to daughter. Females are more liable to it than males. Mothers with ozena sometimes have two or three daughters with the disease, while sons escape. He has found no connection between ozena and tuberculosis or syphilis. For treatment he has obtained good results in the earlier stages by application to the mucous membrane of phenolumnatrosulforicinoseum in 30% solution, two or three times a week.

A long and exhaustive monograph by Alexander [5] reviews the theories which have been advanced to explain this disease, and from them builds up an explanation of the different conditions, adding the hypothesis that, from the primarily diseased underlying bone, pathological substances permeate the mucous membrane and cause the atrophy and other changes. Disease of the bone is the primary pathological disturbance. The earlier in life the disease starts, the more pronounced are the characteristic bony appearances, infantile nose, small turbinates, etc. It may begin in fetal life. The atrophy of the mucous membrane and other structures is caused in some way, probably chemical, by the bone disease. The crusts and fetor are accidental

complications of the diseased mucous membrane and glands. The process extends to the lymph glands and mucous membrane of the pharynx and larynx.

In another paper [6] he discusses the relation between ozena and syphilis; although unable to obtain any positive reaction by Wassermann's test, he argues for a possible or even probable connection between the two diseases.

NASAL TUBERCULOSIS.

A few recent papers on nasal tuberculosis, while not materially adding anything new, serve to review and fill out our present knowledge. Such a composite description is given by Freer.[7]

Custom still retains the name "lupus" for a group of cases of nasal tuberculosis possessing special features. The usual classification of the various forms of nasal tuberculosis is that of Gerber [8] adopted by Gleitsmann. Nasal tuberculosis is divided, according to its aspect, into four forms — the tuberculous ulcer, the tuberculous tumor or tuberculoma, the diffuse infiltration and the formation of granulation areas, the latter being the variety characteristic of lupus.

In the first group of cases, to which belong most of those secondary to pulmonary or laryngeal phthisis, ulceration is the chief characteristic of the affection. The tuberculous infiltration which precedes the ulcer is rarely seen as it creates no symptoms. While the tuberculous ulcer is seldom rapidly destructive, it produces perforations of the septum.

The tuberculous tumor is usually solitary, and, like the other forms of nasal tuberculosis, often appears upon the cartilaginous septum, and next in frequency upon the inferior turbinated body. It varies in size from the bulk of a pea to growths large enough to be mistaken for sarcoma. Nasal tuberculoma may be spherical or lobulated, may have a papillomatous, smooth or irregular surface, and may be pedunculated, but it has usually a broad base.

The tuberculous infiltration, like the edematous form of laryngeal phthisis, with its deep-seated tuberculous infiltration, produces diffuse swelling of the part in the nose attacked, which is usually the cartilaginous septum. In marked cases the thickened septum may appear like a tumor filling both nares.

The form of intranasal tuberculosis typical of lupus is the granulating area upon the mucous membrane. It commonly begins, as do the other varieties, upon the cartilaginous septum, and appears as a bed of grayish-red granulations, producing a surface like that of a raspberry, commonly hidden by scabs. Later in the disease the granulations also appear upon the lower turbinated bodies.

Nasal tuberculosis is commonly a benignant and often primary form of tuberculosis in a tissue little susceptible to the disease and permitting but few bacilli to penetrate it. If, therefore, the tissue invaded can be completely removed, recovery without a relapse is a possibility. Even in lupus, and still more in common nasal tuberculosis, secondary deposits, in the form of pulmonary tuberculosis, tubercular meningitis, tubercular lymphomas, joint disease or some other forms of tuberculosis, are to be feared as long as the primary affection in the nose is not extirpated. As compared to its location in other organs, primary tubercular disease within the nose is somewhat favorably situated for the thorough surgical extirpation which its dangerous and obstinate nature demands as the treatment of choice in case it be deemed feasible. As compared to surgical excision, all of the other methods of treating nasal tuberculosis are far less certain in their results, some being but vaguely experimental.

A paper by Renner [9] read at the same time records a case of typical tuberculoma of the septum. The proliferative form of nasal tuberculosis is considered to be primary. It occurs usually in people of robust health who have no other active tubercular lesions, although evidences of latent tuberculosis may be found in other organs. The tuberculous tumor or tuberculoma is of the type of so-called primary infection of the nasal septum.

Onodi [10] considers tuberculosis of the cartilaginous septum of rather common occurrence. Where the whole disease can be removed by a reasonable operation, it should be done; otherwise, even if there is improvement, relapses are frequent.

Gerst [11] has found nasal tuberculosis in several cases which showed little or nothing abnormal except under the microscope. By this he demonstrated typical foci under the unbroken mucous membrane of the turbinates.

PALATO-PHARYNGEAL ADHESIONS.

Roe [12] discusses fully the etiology, characteristics and treatment of various forms to date. He then reports four cases. Three of these were treated by the suture method of Nichols, and the last by a plastic method devised by Roe. Nichols' suture method is described as follows: Silk sutures are introduced at the side of the palate and allowed to remain *in situ* until a healed channel has taken place around them. The palate is then liberated between these channels, great care being taken not to wound the outer wall of the channel. Roe modified this procedure by the use of silver wire instead of silk. He does not state the advantages of wire over silk. The latter would seem to have at least one advantage in being much more comfortable to the patient. In Roe's fourth case the suture method was tried and proved ineffective because of the thickness of the adhesions, which prevented the formation of a healed channel. At the operation for liberating the palate he found the healing had extended but a short distance beyond the mucous membrane. Having freed the palate from the posterior wall of the pharynx, he concluded to cover the raw surface on the palate side of the opening with a flap. His description of the operation is as follows: "As it was necessary to cover but one surface of this opening, the

anterior or palatal side was most available. In order to secure the mucous membrane for this purpose, a broad flap was taken from the side of the palate and inside of the cheek, including sufficient submucous connective tissue to assure its vitality. This flap was then brought down and turned backward and upward around the outer and lower border of the soft palate and stitched at the sides and the free border through it to the palate along the upper end of the flap that had been turned up behind. The palate was stitched to the latter with sutures passed directly through the palate. Complete union of this flap took place and on healing there was no undue contraction at the site of these flaps nor was there the slightest tendency for the readherence of the soft palate to the pharynx at any time."

Roe recommends this method in preference to the suture method as being much quicker and causing less discomfort.

THE FUNCTION OF THE TONSILS.

What the function of the tonsils may be, or whether they have any function at all, is a question which has not yet got beyond the stage of guessing. This guessing has been going on for some years and has resulted in a fairly voluminous literature. A paper by Levinstein, [13] though long, is interesting because the author, who is an assistant in Fraenkel's clinic, reviews the history of the discussion and argues either for or against many of the theories which have been brought forward. It is true that as a result of this and much previous study of the tonsillar ring his conclusions are rather colorless, agnostic and generally not original, but this result is not necessarily the fault of the author. Many of the theories the author believes may be discarded for more or less obvious reasons. That the tonsils and other lymphoid structures in the pharynx are a protective mechanism against infection he rather doubts, because if this were the case these structures themselves should be the last in this neighborhood to become the seat of infectious processes, whereas they appear generally to be the most vulnerable points.

The important and interesting question whether certain infections of the tonsillar ring are primary or secondary infections he answers by arguing that both forms exist and that in many cases it is doubtful. The acute tonsillitis which follows nasal operations is due to infection brought to the tonsils from an outside focus. The tendency of secondary syphilis to show itself there is an instance of an infection brought through the blood stream, but also clinical experience shows that local infection, such as diphtheria and perhaps tuberculosis, find the tonsils the weakest point of resistance.

Whether the tonsils have any function in childhood, or whether they are examples of atavism, has not been proved either way. He doubts whether they have a protective function, and, on the other hand, he does not believe that they are responsible for all sorts of infectious diseases. In spite of his disbelief in the virtues, and agreeing to the weakness of the tonsils, the author is conservative in his treatment. He lays stress upon local cleanliness of the mouth, pharynx and nose. It is a little startling to find him advocating the galvano-cautery for the purpose of making the tonsil more resistant. He says that it is useless to try to take the whole tonsil out because it may be reproduced. He has perhaps not seen tonsillectomy. It is difficult to criticize his statement that clinical experience proves his point, except to say that it often seems to prove many illogical methods of treatment.

A monograph by the same author [14] on the appendix of the ventricle of Morgagni is an interesting contribution to the anatomy and physiology of the tonsillar system. This so-called appendix is actually a tonsil, differing from the other tonsils in being placed in the depths of a cavity instead of lying on the surface of the mucous membrane. The histological study of this laryngeal tonsil points to the conclusion that the function commonly ascribed to it, that of lubricating the vocal cords, is probably correct. The interesting inference is drawn that, as we can prove this function for the tonsil without doubt, it is possible that a similar function is served by the similar tonsils of Waldeyers' ring.

In an earlier paper [15] he reviews the histology of the follicles of the lateral and posterior wall of the pharynx, which are practically supernumerary tonsils and adenoids.

CHRONIC LARYNGEAL STENOSIS.

In the treatment of chronic laryngeal stenosis, two methods of treatment have their respective advocates. One of these, progressive dilatation of the stricture by means of modified O'Dwyer intubation tubes, is advocated by Delavan.[16] He points out that to accomplish the continued dilatation and consequent pressure atrophy, modification of the O'Dwyer tube is necessary as shown by Rogers.[17] The "normal tubes" designed by O'Dwyer were made to fit somewhat loosely the average larynx and to exert the least pressure compatible with retention of the instrument. In cases of stricture a special tube is necessary for each case in order to effect the desired dilatation. To determine the dimensions of this tube, the patient is put under deep general anesthesia and a number of graduated normal tubes are passed through the larynx until one is found in which the retaining swell distends the constriction to the limit which the operator judges it will bear without causing a slough. Inasmuch as the retaining swell lies just below the cricoid where the stricture is narrowest, and in the trachea which is capable of considerable distention without damage, quite a little force in this test tubage is permissible. Having thus determined the largest possible diameter of the larynx, a special tube is made, of the length of the normal tube, suitable for the age and development of the patient, but with a retaining swell having the same diameter as that of the trial tube. The neck of this special tube should be as large as possible, but its transverse diameter must be 3-32 in.

less than that of the retaining swell or it may be coughed out. Also the head of the tube must be 6-32 in. greater in diameter than the retaining swell to prevent downward slipping. Tubes should ordinarily be made of hard rubber, but occasionally, in obstinate cases, metal tubes are more effective. Some cases will cough up any tube which can be inserted. Under these circumstances it is generally advisable to open the trachea and through the opening clamp or plug the lower end of the intubation tube. In very tight, fibrous strictures, urethral sounds should be used for dilatation from below upward through a tracheal opening before inserting tubes from above. The duration of intubation varies from one month to four years. A fibrous stricture usually requires treatment for two years. Hard rubber tubes should be removed and cleaned once a month and metal tubes oftener. Mayer [18] devised a hollow introducer of intubation tubes for use in cases where the introduction is slow and difficult with danger of asphyxia. Simpson [19] and Johnson [20] report cases of successful treatment of laryngeal stenosis by intubation. The latter emphasizes the value of direct laryngoscopy in the diagnosis and treatment.

A noteworthy advance in the technic of intubation in cases of chronic laryngeal stenosis is to be credited to Winslow [21] and Mosher [22] who, working independently, both performed the operation under direct vision. Mosher has devised an apparatus for this purpose which he has demonstrated to be practical. The advantages of this method are obvious.

The second method of treatment referred to is laryngo-tracheostomy. The method of prolonged intubation is considered unsatisfactory by many of the recent writers on the subject on account of the length of time and the frequent occurrence of auto-extubation. The operation of laryngo-tracheostomy which was first devised by Killian and later modified by Sarguon and Barlatier is described by Delsaux [23] as follows: The operation is divided into seven stages: (1) Median incision through the soft tissues of the neck to the larynx and trachea. (2) Longitudinal division of the larynx and trachea. (3) Suturing of the mucous membrane of the larynx to the skin on each side. (4) Median division and excision of the scar tissue. (5) Introduction of the tracheal canula and rubber dilator. The latter is a soft rubber drainage tube which occupies the lumen of the larynx and trachea with an opening in front below the larynx through which the tracheal canula is inserted. (6) Dressing the wound. This consists of two parts; The first keeps the dilator in place within the laryngo-tracheal tube; the second consists of an external dressing on the canula. Frequent change of dressings and cleansing of the wound and tubes is recommended for a few days after operation. Liquid food is given through an esophageal tube. The duration of dilatation in a series of thirty-six cases reported by Delsaux varied from half a month to nine months and was followed by closure of the opening by plastic operation. He reports cures in 39% — 33% under treatment — death in 14% and failure in one case.

Winslow [24] has used successfully a specially devised T-shaped hard rubber tube for maintaining the dilatation after laryngo-tracheostomy.

Iwanoff [25] has done laryngo-trachesotomy successfully in cases of stenosis resulting from perichondritis of the larynx.

Jackson [26] reports seven cases of laryngostomy. He prefers a soft rubber tube for dilatation, which is either fastened to the tracheal tube below or attached to a spur which runs upward from the tracheal tube.

Sieur,[27] Baumgarten, [28] Ucherman [29] have made contributions to this subject. Lack [30] has found in children with laryngeal stenosis in whom tracheotomy had been performed for diphtheria, and who were subsequently unable to breathe after withdrawal of the tracheotomy tube, that the fault lay in the site of the tracheotomy, which was too high. In these cases he has found that, following a lower tracheotomy, the patients gradually begin to breathe better and are sometimes finally able to dispense altogether with the tracheal tube. He accounts for the enlarged lumen by natural growth.

In stenosis from abductor paralysis Gleitsmann [31] performed thyrotomy and excised both vocal cords in a patient sixteen years of age. An apparently successful result was followed by death seven weeks after operation from pneumonia subsequent to endo-laryngeal curetting of granulations.

TUBERCULOSIS OF LARYNX.

Casselberry [32] divides cases of tuberculosis of the larynx into three types, — the non-resistant, the hopefully resistant and the type capable of arrest. He describes briefly treatment by the more commonly used methods and agents. His conclusions are: (1) Tuberculous hyperplasia in the larynx has not infrequently undergone resolution in whole or in part. (2) Unmistakable tuberculous ulcers have occasionally healed and remained healed. (3) Favorable negative qualities have characterized in common the cases which have proven to be capable of arrest or recovery; for instance, the laryngeal hyperplasia has been less progressive, less diffuse and less prone to ulceration; the underlying pulmonary infection has been less extended; there were fewer tubercle bacilli, a lower pulse rate and less emaciation. (4) These qualities persisting, the cases which are capable at least of a hopeful resistance can be differentiated, thus justifying every effort at any sacrifice to invoke the methods likely to arrest the disease and lead to recovery, including intralaryngeal surgery, when the lesions in degree and kind are suitable for it. (5) In like manner the non-resistant type should be recognized and those patients guarded from privation and distress which surely follow in the wake of an indiscriminate exposure to the elements and to the hardships of travel in distant climes. In them surgery is contra-indicated, excepting to prevent air hunger and suffocation

or to prevent starvation by the removal of some particularly painful impediment in swallowing.

ACTION OF THE DIAPHRAGM IN TONE PRODUCTION.

The common conception of the diaphragm as an inspiratory muscle which by contraction flattens the floor of the thorax and thus enlarges the cavity of the thorax is combated by Makuen.[33] While admitting that the contraction of the diaphragm in so far as it results in flattening the floor of the thoracic cavity does enlarge this cavity, he calls attention to the fact that by reason of its costal attachments the diaphragm in contraction also pulls the ribs inward and thus tends to diminish the size of the cavity. The diaphragm being relatively poor in muscle fibers is not a strong muscle, and its action is not comparable in power with that of the extra-thoracic rib-raising muscles of the upper trunk, nor with that of the rib-lowering muscles of the abdominal wall. The latter, by drawing the ribs downward and inward, are the main factors in expiration, and the former by drawing the ribs upward and outward do the chief work in inspiration. But Makuen goes farther than this and maintains that in the tone production the diaphragm is in effect an expiratory muscle. His explanation of his theory is not clear nor convincing, and he gives no proofs.

In support of the theory that the diaphragm plays an unimportant rôle in respiration and does not flatten during inspiration, but retains its domelike contour during both inspiration and expiration, Boyce and MacLachlan [34] report their investigations with the fluoroscope. On using a tube of the proper penetration, the shadow of the diaphragm was very distinctly seen. It rose in expiration and sunk in inspiration but its contour was not perceptibly altered in any of the series of cases examined. The action was uniformly the same both in males and females.

BRONCHOSCOPY.

Several articles have appeared during the past year on matters related to bronchoscopy. In a paper which he calls "Gleanings from Experience" Jackson [35] records epigrammatically some interesting conclusions:

As far as possible, skill should take the place of anesthetics. Foreign bodies in the esophagus are just as apt to cause dyspnea as those in the trachea. The bronchoscope is a better breathing channel than a tracheal wound.

Respiration is more often arrested in the endoscopic removal of foreign bodies from the esophagus than in tracheo-bronchial cases, though laryngeally lodged cases are worse in this respect than any of the others.

He has reduced his armamentarium to one bronchoscope 5 mm. by 30 cm. for children, and one 7 mm. by 40 cm. for adults.

Foreign body work is a question of mechanics from begining to end.

The simplest, safest and best source of current is a double dry battery, that is, two sets of four cells each. Each set should have two binding posts and a rheostat. All forms of rheostats devised for adapting commercial circuits to tube work are dangerous.

The exposure of the larynx is the whole art of introducing the bronchoscope. Until it is so mastered that the larynx can be exposed and held exposed to view indefinitely, no one should attempt bronchoscopy.

In the dorsally recumbent position, an assistant must be trained to place the parts in the proper position by raising the head at the same time that it is squarely extended on the occipito-atlantal joint, not on the cervical spine.

A widely spread gag may render bronchoscopy impossible by jamming the lower jaw down on the hyoid bone.

The same author, in a joint paper with Gaub,[36] suggests the use of the bronchoscope to maintain pressure within the lung in operations on the chest. In dogs this can be done safely. Oxygen is admitted to the lung by the suction tube of the bronchoscope, and the pressure regulated by the thumb on the main tube. In this way the lung may be inflated or deflated at will, and a sufficient supply of oxygen furnished to both lungs.

In Europe the present theory and practice of bronchoscopy is represented by Brunnings' book. The author, who is the assistant of Killian, has taken charge of Killian's armamentarium and has developed, modified and increased it. The illumination is entirely from the upper end of the tube, and both the tubes and instruments can be lengthened and shortened by ingenious mechanism. The relative merits of these instruments and those perfected by Jackson will for some time be discussed; at present one might be called the European and the other the American method.

Pressure upon the trachea and esophagus has in a series of cases been found by Guisez [37] to be due to an unsuspected aneurism. The diagnosis may be made clear by the bronchoscope.

Casselberry [38] has made a bronchoscopic pin cutter and fragment holder, for cutting long pins which have become pinned into the bronchial tubes. It was successfully used in the case for which it was devised. Similar cases have been reported in which this instrument would have much simplified extraction.

Ephriam [39] substitutes for local applications long sprays for local anesthesia of the trachea and bronchi. He uses applications of alypin 20% for the larynx and a spray of novacaine 10% with suprarenalin for the trachea.

Reports of Societies.

CONNECTICUT STATE MEDICAL SOCIETY

ONE HUNDRED AND EIGHTEENTH ANNUAL MEETING, NEW HAVEN, MAY 25-26, 1910.

THE DIAGNOSIS OF INSANITY. HOW CAN THE GENERAL PRACTITIONER DETERMINE, DEMONSTRATE AND CERTIFY THE EXISTENCE OF MENTAL DISEASE IN A GIVEN INDIVIDUAL ALLEGED TO BE INSANE?

DR. JAMES M. KENISTON, Middletown: To determine the existence of insanity or a psychosis, the examiner should pursue a systematic course. Hence he should get as complete a history as possible. He should first find out just what the patient sees and hears or feels or smells, and whether things are really what they seem to him. Disturbances of memory are next to be noted. Disturbances of the train of thought may be often exhibited and noted during the tests of perception, apperception and memory. Judgment is the loftiest and most complicated of the mental faculties. One can test the patient's judgment in a general way by submitting to him various problems concerning proper conduct, morality, business, etc. It is not enough to know whether he knows right from wrong, and the nature of a criminal act. We should ascertain whether he has lost, wholly or in part, the finer feelings that modern civilization has evolved and society demands. The full fruition of volition depends immediately upon an antecedent idea. Acts performed without a definite idea are not volitional, but reflex. The above details help us to determine the general conduct and show its deviation not only from the patient's norm, but from the standard imposed to-day by society. When the general practitioner has obtained possession of all these facts, and arranged his material, he will be in a position to demonstrate to the proper authorities, or to his confrères, or to the friends of the patient, the existence of insanity. At the Connecticut Hospital for the Insane, up to Oct. 1, 1908, 12,823 patients were committed; and 97 of these, or 0.75%, were diagnosed as not insane. In these 97 cases, a temporary disturbance was mistaken for a more permanent derangement.

DISCUSSION.

DR. MAX MAILHOUSE, New Haven: If the physician will but bear in mind that dementia paralytica often begins with neurasthenic symptoms, and always make his diagnosis by the process of exclusion, he cannot go wrong. In those as to whom there may be a doubt as to whether the trouble is insanity or crime, it is of the highest importance, as the author states, to determine whether the conduct and character deviate from their own norm, as well as from the standard imposed to-day by society. To determine this point, it is not only necessary to question the patient's nearest relatives, friends and associates, but also those absolutely disinterested. The statement of the large percentage of transitory mental disturbances that have appeared in the State Hospital for the Insane seems to me to be a strong argument for the establishment of psychopathic wards in general hospitals.

DR. WILLIAM E. FISHER, Middletown: Despite the fact that we all recognize that the question of the mental health of a community and its preservation are of vital importance, I have knowledge of only one medical college that affords instruction in psychiatry and makes it a part of the curriculum. It would hardly seem necessary to emphasize the necessity of more active co-operation between the alienist and the general practitioner, were there not abundant evidence of a lack of communism of interests. It is is no less possible to group symptoms of the different psychoses so as to afford typical clinical pictures than it is to group the symptoms of a respiratory or a cardiac disease. Much of the difficulty formerly experienced in obtaining clinical pictures of the different psychoses was due to the inadequacy of the methods pursued in restricting the study of the disease to the minute analysis of symptoms at some given period, instead of studying the entire course of the disease. Guard against falling into the habit of seizing upon certain symptoms, ignoring others, and making the clinical picture fit some arbitrarily constructed frame.

GEORGE N. LAWSON, Middle Haddam: I understood Dr. Keniston to say that a man is really responsible for his crimes, very often, even though insane. It seems to me that family physicians are in a position to say more readily than a stranger whether his patient is insane or not, whether he has passed from his own norm and the recognized standards of the day. He can be of great assistance to the staff of physicians at the hospital if he will write up the history and give it to these physicians, along with the certificate of insanity.

INSTRUCTIONS TO PATIENTS SUFFERING FROM SPECIFIC URETHRITIS.

DR. PERCY D. LITTLEJOHN, New Haven: In order to overcome the difficulty of not having my instructions accurately followed by patients, I have prepared some leaflets containing careful directions. I have tried to make the statements contained in them as terse and as clear as possible, and at the same time emphatic. Gonorrhea is not the slight complaint that many consider it. Alcohol must be strictly avoided. Exercise should be taken, but all forms of violent exertion should be avoided. A careful cleansing of the nails and hands is imperative after the gauze dressing is handled. All infected persons should sleep alone, if possible; and all toilet articles must be for their own exclusive use. Particular attention should be given to the alimentary tract, in order to avoid constipation. Few realize the value of drinking large quantities of water and the free urination which this causes. Cases in the acute stage must have a milk diet, as far as possible; and as the disease improves, the diet may be increased. The patient should be cautioned to keep reasonably quiet after his day's occupation is finished. The proper technic in the use of the hand injection should be properly explained. Though I believe that we can cure all cases of anterior infection, and am optimistic regarding the chronic cases, provided the directions are fully followed for as long a time as necessary, and I also believe that cases so treated will not infect other people, yet until all the gonococci can be proved to have disappeared

we are scarcely justified in making a positive statement to that effect when matrimony is contemplated.

DR. FRANK H. COOPS, Bridgeport: Dr. Littlejohn's plan of putting into the hands of the patient printed slips describing the points of the home treatment of gonorrhea, I have seen carried out with splendid results. I have for some time been thinking of getting out such a set of printed instructions, and I cannot do better than copy the set presented, making a few changes to suit my individual fancies. The instruction, "You should drink all the water possible," I should have put in bold type, for instance. When the urethra is washed out every half hour, not enough discharge accumulates to require the use of any dressing at all. The request that the patient come to the office with a plentiful supply of urine in his bladder is of the utmost importance from a diagnostic and prognostic standpoint. I believe, too, that our patients should be instructed as to the import of these various urethral shreds, etc. The disease, under the best of conditions, is a very difficult one to cure.

DR. CHARLES S. STERN, Hartford: The total elimination of red meat would in some cases retard the cure by reducing the patient's resistance. A patient is much more likely to constantly renew a small bit of cotton than a large piece of gauze. Unnecessary handling always increases and continues the local inflammation. I should add as a conclusion to the other instructions, and in heavy type, "Don't stop treatment until you are completely cured."

DR. GEORGE BLUMER, New Haven: It is now known that the white meats have rather more extractives than the red. If meat be stopped, it should be meat of all kinds.

DR. RALPH A. MCDONNELL, New Haven: I have been unable to satisfy myself that diet has any influence upon gonorrhea after the acute part of the infection is over. I think that the drinking of water should be controlled during the latter part of the evening.

DR. LITTLEJOHN, closing the discussion: I was well aware that white meats have more extractives than red, but I knew that if my patients did not eat red meat, they would get very little meat of any kind. People with a recent infection, never having had any previous trouble of this kind, should be told what to avoid in the way of eating; in chronic cases, it does not make nearly so much difference.

THE MANAGEMENT OF SYPHILIS.

DR. ALFRED G. NADLER, New Haven: I do not believe that syphilis is on the increase. Begin treatment as soon as the diagnosis is made, which is usually at the first visit or very soon thereafter. The microscope will almost invariably make or confirm the diagnosis of chancre. The chancre should be excised, but the patient should be subsequently treated just as if this operation had not been attempted. Mercury may be given externally, internally and by injection. The internal administration is not to be resorted to unless conditions prevent the use of inunctions or injections. Treatment by suppository is also inefficient. Administration by inhalation is one of the best methods. I have had no experience with intravenous injections. The advantages of intramuscular and subcutaneous injections are that there is greater regularity of treatment, the absorption is more certain, the stomach is left free for the reception of other medicines, there is less chance of stomatitis, the physical effect is more marked and they are convenient for the patient. Pain may accompany the injections; and sometimes a deposit of mercury is left, which suddenly absorbs, producing poisonous symptoms. The intramuscular injection of insoluble salts produces a deposit which is slowly absorbed and slowly eliminated; when injected subcutaneously, the salts are absorbed and eliminated more rapidly and should be used when a prolonged action is required, but the intramuscular injections have a more profound effect upon the deeper manifestations of syphilis. The first two years of the treatment is the most important period for the patient, but treatment should be actively pursued for at least five years. One should watch carefully for complications. I consider inunctions preferable to injections, and believe that it is better to treat too long than not to treat enough.

DR. RALPH A. MCDONNELL, New Haven: I always find it inconvenient to cut the chancre out, and one cannot promise the patient that cutting it out will do any good, so I do not see any advantage in insisting upon it. I do not find it so easy to discover the spirochetes with the microscope as is indicated by the paper, so I am not able to make the diagnosis by means of the microscope, although it can be done with proper technic. I am not sure that my inability to find the spirocheta does not work to the advantage of the patient, as I believe that, unassisted, the system acquires a certain power of opposition to the disease as time goes on. It is well to let the patient go untreated for a time, even when the diagnosis is made. My preference is for the injection of an emulsion of metallic mercury, which I have given in over one thousand injections without untoward results. I have seen various late manifestations of the disease, and even total blindness, years after the infection, controlled after a few injections.

DR. THOMAS M. BULL, Naugatuck: Physicians should be more careful to diagnose syphilis. If one contagious case be left undiagnosed, an untold amount of harm may be done. Inasmuch as 99% of medicine is given by the mouth, and as this is the natural way for anything to enter the blood, I must confess to a predisposition for this method. There is little danger of irritating the digestive tract if you see the patient frequently and grade the dose carefully. Although the disease is capable of producing the most terrible consequences, I believe it to be the most easily treated of any of equal gravity. I should strongly advise any patient who has ever had syphilis to take a month's mixed treatment every year, whether symptoms have developed or not. The best treatment must be prophylactic.

DR. CHARLES C. BEACH, Hartford: In treating syphilis successfully, it is absolutely essential to make the diagnosis early. I presume that the ideal treatment is by injection or inhalation, but I never use either of these. We get sufficiently good results from the internal treatment by the mouth, and I have found no difficulty in giving the protiodide. We are supposed to keep as professional secrets the names of those that suffer with syphilis, but I believe that cases of this disease should be reported with the same care as cases of scarlet fever or any other contagious disease.

DR. OLIVER C. SMITH, Hartford: The place for such patients is in the hospital, in bed on their backs. They have no right to go about disseminating the disease. We should try to educate the communities in which we practice concerning the great importance of these two terrible infections, gonorrhea and syphilis.

DR. RIENZI ROBINSON, Danielson: I should like to ask the author of the paper whether he would prefer mercurial treatment to the iodide for the tertiary manifestations of syphilis.

DR. CHARLES S. STERN, Hartford: I do not believe that at present the Wassermann reaction has the same standing among physicians as it had a year ago. Either positive or negative, it is not to be depended on.

Dr. Percy D. Littlejohn, New Haven: I thoroughly agree with the statement that gonorrheal patients are better off in the hospital, but you cannot keep syphilitic patients there.

Dr. Nadler: With reference to the Wassermann reaction, I should say that it is not considered so valuable now as it was formerly. I mentioned in my paper that negative reactions do not indicate a cure of the disease. I should treat the tertiary manifestations with intramuscular injections of calomel, and give potassium iodide. I did not enter into the sociological question at all. Chancre may be located where it can be conveniently removed; and in that case, its removal will eliminate a host of infecting agents. I think that the spirocheta can be readily discovered under the microscope with the so-called dark-ground illumination.

A CONSIDERATION OF THE ANATOMY AND CLINICAL IMPORTANCE OF THE SUBDELTOID BURSA.

Dr. Paul P. Swett, Hartford: Lesions of the subdeltoid bursa are more frequent than other lesions in this region, including fracture and tuberculosis of the shoulder. The old term, "peri-arthritis of the shoulder," is not definite, and usually refers to subdeltoid bursitis. The exposed position and peculiar function of the bursa render it especially liable to inflammation. Although the vast majority of cases are best treated by excision of the bursa, there are many instances in which limitation of motion does not exist; and treatment of this class of cases by means of rest, massage and counterirritation is usually sufficient. A diagnosis of rheumatism, tuberculosis, paralysis, ankylosis or neuritis should not be made until the possibliity of subdeltoid bursitis has been excluded.

Dr. Ernest W. Arnold, New Haven: The investigations regarding the subdeltoid bursa are the logical outcome of the investigations regarding the behavior of bursæ in general. The bursæ at the knee-joint inflame without cause. There are a certain number of cases in which no great trauma has been received, and repeated slight trauma from kneeling cannot be held responsible for the chronic inflammation of the patellar bursa. There must, then, be accepted the possibility that these bursæ partake of the same inflammations that the joint itself is liable to have. All infections leave the bursa permanently thickened; and such a bursa must be not only useless, but a great hindrance to the function of the joint. It should be removed, if the impediment to the joint is mainly due to the bursa. We all know that a good many cases will clear up under other treatment, however, than operative interference.

Dr. Ansel G. Cook, Hartford: Here is a new bursa that must be reckoned with. All that is true of the other bursæ is true of this one. Fixation *per se* has never been proved to cause the inflammation of any bursa, but if the arm is fixed in such a position as to cause pressure, that pressure will be trauma. I have given prominence to this point in order to show that we need not be afraid to fix any of these joints, if necessary. There are times when an inflamed joint will do better at rest, and other times when irritation is desirable.

THE IDEAL NOSE AND PHARYNX.

Dr. Frederick W. Wilson, Bridgeport: The amount of air passing through the nose and pharynx in a year must be reckoned in millions of cubic feet. An obstruction having almost no influence in a single inspiration may have great influence in a million inspirations. This is also true of nasal cavities that are too large. Laboratory experiments give expired air a much lower percentage of micro-organisms than inspired air, most of the organisms having been deposited on the moist mucous membrane of the nose and pharynx and being subsequently blown on to the handkerchief or expectorated. The nose and pharynx might almost be called the filtration apparatus of the air. These organisms rarely breed and do harm on a plane surface; they must have some hiding-place where they can lodge and multiply. The ideal nose and pharynx contains as few of these hiding-places as possible. We as a profession are not fully alive to the importance of the existence of small, unnecessary hiding-places and of their complete obliteration by surgical means.

Dr. Dorland Smith, Bridgeport: Nasal surgery for the prevention of consumption is, at first thought, somewhat startling. I have, however, for some years been making careful search for small defects in the nose and pharynx, and obliterating them. We are used to the correction of large defects, but the idea of making an ordinarily well person perfectly well by paying attention to small defects is a further step in development. The acquisition of a good nose and pharynx not only gives one practical freedom from colds, catarrh, sore-throat and the air-borne diseases generally, but also gives one a higher level of health; and this may be given to almost any one who will take the time and trouble to have done those little bits of surgery that make the nose and pharynx approach the ideal. In cases of the removal of tonsils and adenoids, I am satisfied that the certainty of permanent cure and ideal end-results is to be found, not in thoroughness in extirpating tonsil tissue, but in thoroughness in searching out crypts and pockets and recesses that will admit a probe, and in converting them into shallow saucers by trimming their edges. In small tonsils, it is the pockets and adhesions, and not the smooth tonsil-tissue, that make the trouble.

Dr. Wilson: We have definite and positive evidence that these small pockets are of importance in influenza, hay fever, asthma and other minor diseases. We have not the clinical evidence, however, that they are important in pneumonia, tuberculosis and other general diseases; and this is the point upon which we need the help of the general practitioner.

THE TREATMENT OF INFECTION FOLLOWING ABORTION, MISCARRIAGE AND LABOR.

Dr. Charles A. Monagan, Waterbury: The ideal treatment is preventive, — the development of a complete, rigid, aseptic technic. The general use of rubber gloves cannot, unfortunately, be enforced. When the condition is actually present, before the system has become loaded down with bacteria, the uterus should be curetted with a blunt curette. Now, if, at any time, intra-uterine douches may be of service. Antistreptococcic serum has been disappointing in its results. As the prognosis of this grave condition changes very rapidly, undue credit is sometimes given to the remedy last used. The autogenous vaccine treatment has not had very good results, especially in cases of the acute type. The application of hyperleucocytosis often fails to arrest the contagion. I have not seen any good results follow the use of unguentum Crédé. Ergot does good by contracting the uterus, thus preventing further infection. The medical treatment is the ordinary supporting treatment used in fighting any toxic condition. All drugs irritating to the stomach should be avoided. The patient's strength should be kept up by a liberal supply of nutritious food. Salt solution in large quantities is the best single means of controlling the inroads of sepsis. The temperature should be controlled with wet packs, sponging,

cold baths and abdominal coils. Opening into Douglas's pouch and packing with iodoform gauze has been advocated; also hysterectomy for those cases that fail to improve after curettage. The latter procedure would be of use in cases caused by the presence of a suppurating tumor. In septic peritonitis, multiple incisions, thorough drainage and the constant use of saline rectal infusions offer the best means of treatment. If a collection of pus can be located, it should be opened and drained.

Dr. Samuel M. Garlick, Bridgeport: While I would not abate one iota of the needful care in all cases of labor, I am far from convinced that every maternity case should have the same preparation and management as an abdominal section requires. The modern woman, with her highly apprehensive organism, is often brought to the verge of a state of nervous breakdown by the anticipation, worry and fear engendered by such elaborate, detailed and expensive preparation. So often has my hospital experience shown me the bad results of indiscriminate and routine curettage that I am sometimes led to wish it had never been introduced. Antistreptococcic serum has been disappointing in my hands or under my observation. With autogenous vaccine treatment, I have had no experience. Two cases of hysterectomy for septic metritis have proved fatal. I have had no experience with unguentum Crédé.

Dr. Ralph W. Crane, Stamford: Dr. Monagan outlined one method of treatment after another, as did Dr. Garlick afterward; and both said that these were all no good. The fact is that the treatment is prevention, as Dr. Monagan said in his opening sentence.

Dr. Thomas G. Sloan, Hartford: I recently saw in consultation the case of a woman who died, at the end of ten days, of puerperal septicemia. It did not seem that she could have been infected by the man who delivered her. I do not think that any douches were used previous to the confinement, and no nurse came in contact with the patient in a way to infect her. The woman's mother and sister had both died of puerperal septicemia. Where the infection came from, except from the vagina, it is impossible to say.

Dr. Allen H. Williams, Hartford: If the patient realizes that perfect cleanliness will insure her recovery, care of that sort will not scare her. The meaning of these precautions should be explained to her.

THE SURGICAL TREATMENT OF GASTRIC AND DUODENAL ULCER.

Dr. Everett J. McKnight, Hartford: The surgical treatment of gastric and duodenal ulcer and their complications shows a lower mortality and a higher percentage of permanent cures than can be produced by medical treatment alone. None of the complications or sequelæ, except hemorrhage, usually occurs early in the disease; and it is a question whether a perfectly healed, non-indurated scar following ulcer ever gives rise to further trouble. The healthy stomach has the same tendency to recover from injuries caused by traumatism as has any other healthy organ. In cases that do not recover, some extra factor is at work. Investigations point to hypersecretion and hyperchlorhydria as the most important factors in preventing the normal process of repair. The beneficial effects of a gastro-enterostomy are due to regurgitation of biliary and pancreatic secretions into the stomach, neutralizing to some extent the excess of hydrochloric acid rather than to a better drainage of the stomach. I prefer the grouping of symptoms used by Graham in the *Journal of the American Medical Association* for Aug. 22, 1908. If the ulcer is located in the abdomen, gastro-enterostomy is the operation of choice. In gastric ulcer, however, the removal of the ulcer is the only proper procedure for some cases, although in a majority of cases a posterior gastro-enterostomy is sufficient. Operation is rarely needed for the control of hemorrhage itself. One of the most serious complications of ulcer is perforation, which is more frequent when the ulcer is situated on the anterior wall. The results of operation performed during the first few hours after perforation are exceedingly good. The patients should be watched as carefully after the operation as before, until a sufficient time has elapsed to enable the attendant to be certain that a permanent cure has been effected.

DISCUSSION.

Dr. Oliver C. Smith, Hartford: It takes a reasonable length of time to determine whether medical treatment is to be successful or not. After this, the ulcer becomes a surgical disease. The fact that conditions lower down develop symptoms so similar to those of gastric ulcer that they are confused with it has been referred to; and the fact that many carcinomas develop on the basis of a gastric ulcer emphasizes the importance of early operation. It is not possible to tell before operation just what condition we are dealing with, and this argues for more frequent resection of the portion of the stomach bearing the ulcer. We should use a soluble material for sutures in the inner coat.

Dr. Edward W. Smith, Waterbury: It is very unusual to find present in one patient a healed ulcer and the production of symptoms of pyloric stenosis due to conditions lower down in the intestines. I have seen a case that showed these points. He had had a peptic ulcer that had been healed by medical treatment. He then had pylorospasm simulated by an irritated appendix. When you have a gastric ulcer, the appendix had better be looked out for also.

Dr. William H. Carmalt, New Haven: I think that Dr. McKnight has not made so much of the symptomatology of supposedly cured cases as he should. The condition of relief obtained from a course of medical treatment is not a cure, but simply a temporary condition of improvement. When several such series of symptoms occur in a patient, it is time to cease medical treatment.

Dr. William F. Verdi, New Haven: I should like to call attention to the fact that there is a difference between a chronic ulcer and a perforating ulcer. Perforating ulcers come on, as a rule, in persons between twenty-eight and thirty years of age. The symptoms are not usually severe, and the patients are able to continue their work. They are usually seized with the perforation while at work and are brought to the hospital suffering intense pain that requires immediate relief. At first, it is the right half of the abdomen only that is affected. The intestinal contents are poured out under the surface of the liver and go toward the right iliac fossa. The chronic ulcer is different. The patients have a long train of symptoms, going on over a number of years; and in these cases there is not much danger of perforation because the ulcers are protected from perforation by a great many adhesions that form about them.

Dr. Louis M. Gompertz, New Haven: It is extremely important for the medical man constantly to bear in mind that ulcers of the stomach and duodenum are much more common than is usually supposed. When patients complain of pain on an empty stomach, relieved by eating food, and then coming on again within two to four hours, one should be

suspicious of the presence of an ulcer at the pylorus or lower down. When an early diagnosis is made, the very acute ulcers are sometimes benefited by medical treatment, but it does not make any difference how you treat patients with chronic ulcers, for they will still have the ulcers. If you wish them cured, send them to the surgeon for operative treatment.

DR. MCKNIGHT: We are all coming to feel that, for ulcer of the stomach, resection or partial gastrectomy is the operation of choice, considering the large numbers of cancers that develop on the basis of ulcers. I have operated on more cases of appendicitis that simulated gastric disease than I have on gastric ulcers; so these cases are not so rare as Dr. Edward W. Smith thinks. Regarding Dr. Verdi's distinction between the two classes of ulcers, I would say that in the case of a man of fifty-five years there was a chronic ulcer with sudden perforation.

THE TREATMENT OF FRACTURES.

DR. GEORGE W. HAWLEY, Bridgeport: The treatment of fractures does not appear to have kept pace with the advance of modern surgery and does not meet present-day needs. The enormous number of persons that are crippled every year as the result of fracture offers a challenge to surgical science. This industrial age will soon ask what is being done to lessen the great industrial loss through fractures. There is room for common-sense in laying down principles on which treatment should be based. In all fractures, the bones tend to unite without assistance of any kind. The most that we can do is to help nature to obtain useful union. The only way to do this is by approximating the ruptured tissues, on the principle that the more accurate the approximation, the more perfect will be the repair. There is need for better means of holding divided bones in apposition, and there is opportunity for improvement in the technic of operations on fractures, based on the fact that bone stands trauma or infection but poorly. There is no reason why we should not repair an injured bone as readily as we would any other injured structures, and there is great reason to believe that the future will see an increased interest in fractures and a creditable advance in their treatment.

(To be continued.)

Book Reviews.

A Manual of Personal Hygiene. Proper Living upon a Physiologic Basis. By American authors. Edited by WALTER L. PYLE, A.M., M.D. Fourth edition, revised and enlarged. Philadelphia and London: W. B. Saunders Company. 1910.

This volume presents in popular form the physiologic rationale of personal hygiene, under the subjects of the digestive apparatus, the skin, the respiratory system, the ear, the eye, the brain and nervous system, and physical exercise. To these original topics, this fourth edition adds a section on home gymnastics, new chapters on body-posture and domestic hygiene, and an appendix describing the elementary principles of hydrotherapy, thermotherapy, mechanotherapy and first aid to the injured. Representing though it does the work of ten different authors, the book has, nevertheless, a unity of purpose as a manual to teach the principles and methods of physical right living from the legitimate didactic standpoint of the physician.

The Diseases of the Nose, Mouth, Pharynx and Larynx. A Textbook for Students and Practitioners of Medicine. By DR. ALFRED BRUCK (Berlin). Edited and translated by F. W. FORBES ROSS, M.D. Edin., F.R.C.S. Eng. Assisted by FREDERICK GANNS, M.D. Illustrated by 217 figures and diagrams in the text. New York, Rebman Company.

This is a book of six hundred pages, covering the subjects of its title briefly and systematically. It was written in Germany, translated in England and is offered as a manual to American students and practitioners. There are several similar textbooks published by Americans, and it is interesting to note the more striking differences between them and this one. Here the ear is not included, but instead there is a division for the mouth. This is a good arrangement. The common diseases of the mouth and tongue should logically be taught with those of the throat, and practically are often treated in laryngological clinics, yet they are seldom included in laryngological or other textbooks in common use. The ear, on the other hand, has its own manuals, and even when written by the author of a manual on the throat it might with advantage be bound separately, if only for ease in handling. In addition to the division for diseases of the mouth there are included other subjects of more or less importance which should be welcome in a book of reference, as examples of which may be mentioned: Sycosis of the Vestibule, Mumps, the Examination and Pathology to the Trachea, the Voice in Singers. On the other hand, it is startling to find the whole description of operative treatment of deviations of the septum, including the Ashe operation and submucous resection, occupying less than a page. It is perhaps less surprising that the occidental interest in the tonsils, and especially their removal, should not yet have found its way into the book, except to say " that various authors, and recently Winkler also, advise evulsion "; but the description of how or why tonsillectomy is done is dismissed in a few lines. These are the two weakest points in the book. The pages on anatomy are brief and clear. Many of the illustrations, although not all original, are good. The text is better arranged for reference than is often the case in German manuals, and it is well printed. The object of the author is to state briefly the essential points, and to leave out nothing of importance. This he has succeeded in doing well, with but few exceptions, and the result is a book which will be found useful both to the student and to the general practitioner. It would be a good supplement to most of our American manuals, filling in omissions in some places and giving a different point of view in others.

Contributions to Abdominal Surgery. By the late Harold Leslie Barnard, M.S., F.R.C.S., Surgeon (with charge of Out-Patients) to the London Hospital. Edited by James Sherren, F.R.C.S., Surgeon (with charge of Out-Patients) to the London Hospital; Surgeon to the Poplar Hospital for Accidents, etc. New York: Longmans, Green & Co. London: Edward Arnold.

This is a delightful book, characteristic of certain of our English contemporaries. Barnard died two years ago. He was known as a brilliant teacher, clinician and investigator in the London Hospital, and was beginning to make a great impression on the surgery of his community. This book is a collection of a number of his important recent unpublished papers. The book begins with a sketch of Barnard — charming and sympathetic — by his associate, H. H. Bashford, whose account of the man, of his methods and of his influence is abundantly worth reading. Then there follows an extremely interesting paper, filling much more than half the book, on Intestinal Obstruction, another on Gastric Surgery, another on the Simulation of Acute Peritonitis by Pleuro-pneumonic Diseases, three lectures on Acute Appendicitis, and finally, an extremely important contribution on the Surgical Aspects of Subphrenic Abscess.

To the student of abdominal disease and to the man who delights in terse and vigorous scientific English these essays appeal strongly.

The Medico-Chirurgical Series No. 2. The Stomach, Intestines and Pancreas. By W. C. Bosanquet, M.A., M.D. Oxon., F.R.C.P., Assistant Physician to Charing Cross Hospital and to the Brompton Hospital; and H. S. Clogg, M.S. Lond., F.R.C.S. Eng., Assistant Surgeon, Charing Cross Hospital; Senior Surgeon to the Evelina Hospital for Children. Edited by James Cantlie, M.A., M.B., C.M. Aberd., F.R.C.S. Eng., Surgeon Seamen's Hospital Society; Lecturer on Surgery, London School of Tropical Medicine. New York: William Wood & Co. 1910.

This work is a clear and concise description of its subject both in its medical and in its surgical aspects, but without notable departures from the teachings of previous standard textbooks of medicine and of surgery. To the student approaching the subject for the first time, it offers profitable and easy reading. But for the practitioner of medicine already familiar with the subject in general outline searching for new hints to improve the efficiency of his treatment either medical or surgical there is not sufficient detail. As is stated in the preface, the authors have aimed to produce a concise description of the various diseases rather than an extended scientific discussion. In this they have succeeded admirably.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, AUGUST 11, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 Tremont Street, Boston, Mass.

THE OPIUM TRAFFIC.

The agitation which has been going on for some time relative to the opium traffic in the far East will undoubtedly soon lead to definite results. This is largely due to the untiring efforts of Bishop Brent, of the Episcopal Church in the Philippines. Bishop Brent has been intimately associated with the opium commission since its inception and has devoted much time and attention to the extremely difficult social and political problems involved in an equitable solution of what must generally be regarded as an evil.

For many years a considerable part of the revenue of India had been derived from export to China and the Strait settlements. In the fiscal year 1907–1908 for example, upwards of 48,000 chests of opium were exported with a net revenue to the government of more than $17,000,000. In 1906 the Chinese government promulgated regulations for the control of the growth aud sale of opium and two years later the British Ministry agreed with the Chinese government that 51,000 chests of opium should be considered the standard amount to be imported yearly into India, this amount to be decreased each year by 5,100 chests, the importation finally to cease entirely after the lapse of ten years. It will be realized how important an element the trade in opium is when it is stated that in 1905, 7,270,000 lb. of opium with a valuation of $23,000,000 were exported to China. It is said that the amount of opium grown in China approximates these figures. In 1909 the situation appeared to be sufficiently critical to make desirable the appointment of a commission. The idea of this commission was initiated by the American government and delegates from China, European and Asiatic nations together with representatives from the United States met at

Shanghai. Bishop Brent was made president of the commission and resolutions were forthwith adopted bearing upon the various governments for the suppression of opium smoking. Had these resolutions as finally adopted been as drastic as was originally proposed by the American and Chinese delegates it is probable that the traffic would speedily have been suppressed. The American plan was, however, opposed by Great Britain owing to certain trade relations existing between China and England, and the contention that China was not carrying out pledges made in 1908 relative to the discontinuance of the growth of the poppy.

As in most such undertakings it appears that certain officials are active and others lax in carrying out the regulations looking to the suppression of the opium traffic. It is evident that the interests involved are so comprehensive and concern so many nations that an amicable and satisfactory settlement of the question must involve large diplomatic foresight and a thorough consideration of the claims of the various governments involved. Bishop Brent's experience together with his well recognized reputation for tact and wisdom in handling men and situations will doubtless go far toward rendering a final solution of the question satisfactory to the varying interests involved.

THE MEDICAL STUDENT AND HIS FINANCES.

Among the professions, there is none in which money is so necessary during the preparatory stage as in medicine. To get a good medical education one must spend at least eleven years in elementary, grammar and high schools, or their equivalent, two years in college and four years in the medical school. Following this, a hospital service lasting from one to two years is practically a necessity. Assuming that one begins to study at the age of six, he will be at least twenty-four before he can begin to practise. As a matter of fact, there are very few who graduate as early as this from the schools requiring previous collegiate training. The great majority of men are between the ages of twenty-six and thirty when they leave the medical school. It is not at all uncommon to find among hospital internes men of over thirty.

The cost of such an education, considering only the two years of college and the four years of medical school and reckoning each year's expenses as $500, amounts to $3,000. Occasionally, men spend less than this, but the cost of living in cities, where medical schools are for the most part situated, generally brings the expenses much higher. A number of men offset this expenditure, or a part thereof, by earnings. Even in college, however, the prospective medical student has less chance to earn than men taking a less scientific course. His laboratory work consumes much more of his time, and the subjects in which he is proficient are usually not the subjects in which tutoring is in much demand. When he enters the medical school, he should have all his time and energy for study.

It is easy to see, therefore, that unless a student's family is able to support him for five or ten years after he is of age (a situation frequently more distasteful to the student himself than to his parents) his struggle to get through the medical school without being very deeply in debt is sure to be a hard one. There is one type of man who can meet this problem successfully, but there are also many men of different type, who, although hard workers and equally good students, have not the ability to find satisfactory work. The remedy for these conditions is none too easy to find. Assuming that there is money available for scholarships, it must be turned in the proper direction. Assignment of scholarships according to marks alone is often objectionable, for the really deserving man may be prevented from winning by his efforts to earn his bread and butter. The mere ability to gain high marks, furthermore, is not necessarily the talent which later makes a man useful to his profession.

Harvard University has done wisely in appointing a director of scholarships for the medical and dental schools. As one having authority, this officer may be interviewed by college men long before they enter medicine, and can give them reliable information as to their chances of help. He can single out from among the applicants for aid those in whom the money will be best invested. He is to be empowered to loan small sums, and his office, furthermore, is to be used as an employment bureau. This should make available for medical students whatever suitable positions may exist, and should also serve the public by furnishing them the best men for the vacancies which they would fill.

THE WANDERINGS OF A SMALLPOX PATIENT.

Many persons in New York were recently exposed to the danger of contracting smallpox by the extraordinary actions of a patient suffering from that disease. This was a young German employed in a candy and ice-cream shop in upper Second Avenue. Feeling ill, he consulted a phy-

sician in the neighborhood, who made the diagnosis of smallpox. As soon as the young man heard the word smallpox, he bolted from the office, and in a distracted condition boarded a trolley car. From this he transferred to another car, which took him to West One Hundred and Thirtieth Street ferry, where he crossed to the New Jersey Shore. There he climbed the hill and remained till evening, when he returned by the ferry to New York. By this time, believing that he would surely die from the loathsome disease, his mind was made up for suicide, and, finding a deserted street corner, he drew from his pocket a small revolver which he had always carried since his arrival in this country and shot himself in the head. Curiously enough, the bullet struck a glass eye which he wore in place of one of his eyes, lost by an accident in Germany. From thence it was reflected alongside the skull for several inches, making a shallow but not dangerous wound. This he bound up himself with a handkerchief, and then went back to the room he occupied, near the place where he worked. All that night he suffered from severe pain in the head, and, the pain continuing he rode all the next day in various street cars, in the effort to seek distraction from his trouble. At nightfall he could stand it no longer and accordingly betook himself to Bellevue Hospital. From there, as soon as the diagnosis of smallpox was confirmed, he was sent to the reception hospital for contagious diseases.

MEDICAL NOTES.

Special Poliomyelitis Number of "Pediatrics." — The August issue of *Pediatrics* is devoted to the subject of acute poliomyelitis. Those who contribute are Drs. I. Strauss, Simon Flexner, John M. Armstrong, F. E. Coulter, Colin K. Russell, George P. Shidler, J. S. Fowler and C. A. Anderson. The latter writes on an epidemic of two hundred and seventy-nine cases. In addition to these articles the excellent discussions recently held in Washington at the Congress of American Physicians and Surgeons are published, together with a retrospect of literature on the subject of poliomyelitis. The importance of the disease certainly justifies such comprehensive articles collected in readable and condensed form. It is primarily necessary that practitioners everywhere should learn to recognize the early symptoms of the disease and such knowledge can be obtained in no better way than by such comprehensive statements in medical periodicals.

A Retail Drug Corporation. — Negotiations have been completed for the exploitation of a gigantic retail drug corporation, with a capital of $15,000,000 to be known as the Riker-Hegeman Company. The president is to be John N. Flegler, of the Standard Oil Company, the present head of Hegeman & Co., and the business of this company, with a capital of $6,000,000, is to be united with that of the William B. Ricker & Son Company, with a capital of $2,500,000. The additional $6,500,000 capital will be used for further expansion. Twenty of the drug stores in the new combination have been operated by the Hegeman Company, and twenty-five by the Riker Company, and, as several of these stores are now placed close to each other and compete for the trade of the same localities, it is planned to do away with duplicate stores and to place new ones in other localities in the city. In addition, it is purposed to open stores in Boston, Philadelphia and Baltimore, and possibly to establish a chain of several thousand stores throughout the country.

Exorbitant Prices for Milk. — The Attorney-General of New York State, who has been investigating the matter, asserts that present prices charged for milk are exorbitant. This is certainly very regrettable, and it is to be hoped that corrective measures may be rendered possible. At the same time, it is probable that the average milk supply of New York was never before of so good a quality as at present. The State Commissioner of Agriculture, Raymond A. Pearson, has been very energetic in his efforts to secure purity of the supply. Scores of violations of the ordinances have been discovered, and convictions and fines have followed. The city health department has also been most active in the good work, and, while the milk purveyers as a rule have co-operated cheerfully, the untiring labors of the department have been at the bottom of the maintenance of a high standard. Dr. Darlington, when Health Commissioner, labored diligently to keep the milk sold in the city uncontaminated, a task not easy in a territory extending into Massachusetts on the one hand and as far as Ohio on the other. A recent statement issued by his successor, Commissioner Lederle, shows that in the methods of dairy and depot inspection no falling off of vigilance has been permitted. The closest practicable supervision is maintained over the thousands of dairies furnishing the supply. The work of inspecting all dairies within the state limits is carried on by a corps of trained

men who visit the dairies at regular and also irregular intervals, and for each dairy a score card is kept. Each of them has its rating, and if any falls below the high standard required, its milk cannot be brought into New York until the objectionable conditions are rectified. The requirements from the proprietors as regards cleanliness of premises, cows and milkers are, in fact, more exacting than are usually maintained for private consumption anywhere in this country. In the city, not only are samples of practically all the milk brought in examined at the places of entrance and analyzed in the health department laboratories daily, but a constant lookout is kept over the entire city for local outbreaks of disease which may be traceable to the milk supply.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.— For the week ending at noon, Aug. 9, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 39, scarlatina 17, typhoid fever 18, measles 26, smallpox 0, tuberculosis 67.

The death-rate of the reported deaths for the week ending Aug. 9, 1910, was 15.15.

BOSTON MORTALITY STATISTICS. —The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Aug. 6, 1910, was 195, against 191 the corresponding week of last year, showing an increase of 4 deaths and making the death-rate for the week 16.14. Of this number 96 were males and 99 were females; 189 were white and 6 colored; 136 were born in the United States, 56 in foreign countries and 3 unknown; 28 were of American parentage, 140 of foreign parentage and 27 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 48 cases and 1 death; scarlatina, 19 cases and 1 death; typhoid fever, 24 cases and 0 deaths; measles, 23 cases and 1 death; tuberculosis, 55 cases and 18 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 11, whooping cough 0, heart disease 22, bronchitis 0. There were 12 deaths from violent causes. The number of children who died under one year was 67; the number under five years, 82. The number of persons who died over sixty years of age was 32. The deaths in public institutions were 87.

Cerebrospinal meningitis, 1 case. Consumption, 2 cases and 1 death. Scarlet fever, 2 cases and 1 death. Diphtheria, 2 cases.

Deducting deaths of non-residents, the total is 176 and the death-rate is then 14.57.

WORK OF BOSTON MILK AND BABY HYGIENE ASSOCIATION. — This association is attempting to educate the poorer classes in the care of their children by the wide circulation of leaflets containing striking statements regarding dangers to be avoided and measures to be followed if the health of the babies is to be preserved during hot weather. We quote what are properly termed "Six Imperative Rules for Saving Baby's Life." "Feed baby from the breast wherever possible. Nurse your baby at regular times. Give him pure milk from a thoroughly clean bottle. Keep cool. One cotton shirt and a diaper is clothing enough. Give plenty of fresh air — always have the windows open. If baby is sick, stop feeding altogether, give it plenty of water, and take it to a doctor, children's hospital or milk dispensary." This is a sample of the purpose of these leaflets although they enter very much more into detail than these dogmatic statements alone would imply. We have no doubt such a propaganda is useful and certainly it should be encouraged by the people to whom it chiefly applies.

NEW YORK.

BEQUESTS. — By the will of the late Charles P. Armstrong, of New York, $5,000 each is left to the Methodist Episcopal (Seney) Hospital and the Methodist Home for Aged People in Brooklyn.

A CENTENARIAN. — Daniel Darney of New York, died on Aug. 3, at the age of one hundred years. He was a native of Cork, Ireland, and came to this country forty-six years ago.

APPOINTMENT OF DR. GLENTWORTH R. BUTLER. — Dr. Glentworth R. Butler, of Brooklyn, at present President of the Kings County Medical Society, has been appointed a member of the State Board of Medical Examiners. The term of service is for three years.

STATE MORTALITY STATISTICS. — The State Department of Health reports that in the month of June the total number of deaths reported in the state of New York was 10,893, and the total number of births, 16,782. In New York City the number of deaths was 5,946 and of births, 10,400; thus giving the city all but 1,435 of the total excess of births and deaths, which was 5,889.

NEW ANTI-VENOM SERUM. — An anti-venom serum prepared at the Rockefeller Institute, under the direction of Dr. Noguchi, has just been used

for the first time in the case of a patient at Bellevue Hospital who was bitten in the hand by a rattlesnake which he owned, and it was successful in saving the man's life.

Purchase of Real Estate by Academy of Medicine. — A special meeting of the New York Academy of Medicine was held on July 18 for the purpose of adopting a recent report of the Trustees and Council of the Academy relating to the purchase of real estate property for the use of the Academy, and of authorizing the ratification of the same, in accordance with the provisions of the by-laws of the Academy.

Verdict Against a Hospital. — The Appellate Decision of the New York Supreme Court recently confirmed a verdict for $30,000 damages in the lower courts against St. John's Hospital, Long Island City, in the borough of Queens. The winner of the suit was a bicyclist who was rendered blind in consequence of injuries received by being run over by an ambulance of the hospital. It is not probable, however, that the ambulance service of any of the hospitals in the city will be discontinued as a result of the large amount awarded in this case. Practically all of them have for years been carrying indemnity policies of considerable size with insurance companies to protect them against damage suits of this kind, and, in addition, the city makes most of the hospitals maintaining an ambulance service an allowance of about $1,200 a year.

Death from Administration of Lysol. — The authorities are now investigating the death of a six-months-old infant which occurred at Trenton, N. J., on July 24, from the administration of lysol, given in mistake for laxol, the castor-oil proprietary preparation. The physician who was attending the child, asserts positively that the prescription which he wrote called for an ounce of the latter, while the druggist who put it up claims that the prescription was for lysol. Even granting that the word as written did look like lysol, the druggist is clearly at fault for not calling the physician's attention to the large dose of this poisonous drug ordered before allowing the medicine to go out of his shop.

Hospital for Sick Children. — The plan is now being discussed by the municipal authorities for securing for the use of the city as a hospital for sick children a fine new hospital building recently erected by the national government on Ellis Island, in New York Harbor. This hospital, costing $250,000 and with a capacity of 500 beds, was designed for the treatment of contagious diseases among the immigrants arriving at the island, but the building is now found to be useless for this purpose, as the New York Health Department recently issued an order that all immigrants suffering from such diseases must be detained at quarantine. It is believed, therefore, that the government would be willing to rent the building to the city for a comparatively small sum, and Mayor Gaynor has expressed a favorable opinion of the proposed, provided the rental asked is not too large.

Opening of a Model Tenement House. — In connection with the celebration of the one hundredth anniversary of St. George's Protestant Episcopal Church next year it is purposed to open a large model tenement house, subscribed for by members of the parish. The shares for this undertaking are now being taken up, and it is stated that J. Pierpont Morgan, ex-Mayor Seth Low, Joseph W. Harriman and other men prominent in the business and financial world who are members of the vestry will have only one share each, the idea being that the poorest as well as the richest in the congregation shall be subscribers. The cost of the land and the building, which is to be located in the congested district east of St. George's, is estimated at $200,000. While the church is to raise the money, the actual work of erecting and managing the model tenement will be placed in the hands of the City and Suburban Homes Company, the head of which is Dr. E. H. R. Gould, and which now has a number of such houses in successful operation.

Free Distribution of Ice. — A corporation which does not write to have its name known has announced that it is prepared to give away to the poor ten thousand tons of ice during the present heated term. The institutions and societies designated to make the distribution are the City Health Department, the Charity Organization Society, the Association for Improving the Condition of the Poor and its auxiliary, the New York Milk Committee, the United Hebrew Charities, the Brooklyn Bureau of Charities, and the Brooklyn Children's Aid Society. Each of these organizations will be supplied with tickets which can be cashed at any ice wagon in the city.

Diphtheria at Manhattan State Hospital — An outbreak of diphtheria has recently occurred at the Manhattan State Hospital for the Insane,

on Ward's Island. Sixty or more patients were attacked but vigorous measures were at once adopted by the hospital staff, assisted by physicians of the Health Department, and the disease is now reported as under complete control. Only one death occurred, and this was at the beginning of the outbreak. A few of the cases were transferred to the Willard Parker Hospital for diphtheria and scarlet fever, but most of them were treated in special wards in the institution, and by way of prophylaxis all the inmates and employees were given antitoxin. At the same time, a rigid quarantine was put into force. Of the total number of cases, two thirds were women, and the patient who died was a young woman employed as cook. Investigation has shown that the disease was brought in from the outside.

RECIPROCITY BETWEEN NEW YORK AND NEW JERSEY. — As the result of a recent order of the Board of Regents of the University of the State of New York refusing to recognize the licenses of New Jersey physicians unless such physicians are also practitioners in the state of New York, the Board of Medical Examiners of New Jersey has retaliated in kind by passing a resolution to the effect that on and after Nov. 2, 1910, further endorsement of the certificates of medical licenses issued by the state of New York shall be discontinued unless the agreement of reciprocity between the two states is renewed in the interim. The agreement referred to was made in October, 1906, and remained in effect until a month ago, when the new order of the New York Regents was adopted. A formal request for a reconsideration has been transmitted to Augustus S. Downing, First Assistant Commissioner of Education of New York, by the New Jersey Board of Medical Examiners, and in commenting on the matter, Dr. H. C. Norton, secretary of the latter board, has made the following statement: "The medical statutes of New Jersey have not been changed since the agreement was made, and the standards of examination have not been lowered. The agreement was drawn up after a painstaking examination of the laws of both states. Our medical societies opposed the endorsing of licenses from any state which does not endorse the licenses of New Jersey, and we trust that the New York Board of Regents will be willing to reconsider their action, believing, as we do, that this action was taken without sufficient consideration of the subject and without due regard for the interests of the medical profession of their own state and ours."

1. Knott's experience with 161 cases of appendix abscess leads him to believe that in the majority of cases the appendix should be removed at the primary operation, adhesions towards the pelvis broken up to allow hidden pus cavities to drain, and drainage with a large (one-half inch in diameter) rubber tube instituted, together with the Fowler position and rectal seepage. With this line of treatment his mortality in 161 cases was only 1.4%. He feels that the results are infinitely better than under the former plan of treatment, in which the abscess was simply drained and the appendix left to be taken out at a second, often very difficult, operation. The safety of this radical procedure lies in the fact that with the Fowler position and rectal seepage the great danger of even a general peritoneal infection is practically absent.

9. Reber's most interesting paper is well worth study. He reports 5 cases of ocular palsies in a series of 2,000 spinal anesthesias, and from 66 odd reported cases summarizes as follows: The drugs used have been stovain, novocain, cocaine, eucain, tropacocain and alypin. Stovain leads the list in producing ocular palsies. The dose has varied from 10 to 15 cgm. on the continent, and 5 to 7 cgm. in America. The external recti are the muscles most involved. The average time of onset is about ten days after the spinal analgesia has been induced. This varies

considerably, however; some cases developing in four days, others not for thirty days. It seems that novocain predisposes to an earlier onset of the palsies. Few palsies are transitory: most of them are undoubtedly permanent. The fact that they are one-sided seems to exclude their being of an infectious nature, for these latter are generally bilateral. Babcock, who has given 1,400 injections, is in favor of some decomposition of the fluid used as the cause of these palsies. Reber suggests that careful tests on animals and otherwise of boiled and non-boiled solutions be made in order to discover the cause of this distressing complication.

14. Bigelow reports 3 cases of hemorrhagic disease of the newborn successfully treated with freshly prepared rabbit serum. The dose used was 5 ccm., repeated in twelve hours if necessary. He quotes Neil, who suggests that the dose of 75 ccm. used in the case finally transfused by Murphy was altogether too large as too large doses often produce the opposite from the desired effect. [E. H. R.]

BULLETIN OF THE JOHNS HOPKINS HOSPITAL.

JULY, 1910.

1. *WINTERNITZ, M. C., AND BOGGS, T. R. *A Unique Coincidence of Multiple Subcutaneous Hemangio-Endothelioma, Multiple Lymphangeo-Endothelioma of the Intestinal Tract and Multiple Polypi of the Stomach Undergoing Malignant Changes; Associated with Generalized Vascular Sclerosis and Cirrhosis of the Liver.*
2. TODD, J. L. *A Review of the Recent Advances in our Knowledge of Tropical Diseases.*
3. *ANDERSON, J. F. *Anaphylaxis and its Relation to Clinical Medicine.*
4. REIK, H. O. *An Unusual Case of Cerebral Tuberculosis Following Tuberculous Otitis Media.*
5. *MARSHALL, H. W. *Etiology of Chronic Arthritis.*

1. The title of this paper is self-explanatory. The article is illustrated with twenty-one excellent plates and contains a study of the apparently unique condition under the following headings: (1) Description of the case; (2) protocol of the autopsy; (3) Histological studies; and (4) summary and theoretical deductions.

3. This article is a general review of this subject, with a description of its development and significance.

5. Marshall presents his theory as to the etiology of chronic arthritis as follows: "That the causes of chronic arthritis are chemical irritants in the blood, disturbances of the central nervous system, mechanical pressures and strains and external physical stimuli; and that each etiological factor may be a variable quantity; also that joint tissues themselves have a vital resistance of variable degree." Under irritating substances in the blood he discusses (*a*) chemical products of bacterial growth, (*b*) chemical products derived from gastro-intestinal tract, (c) metabolic products of organ activities and therapeutic drugs, and poisons like lead. Disorders of the central nervous system he believes are a factor chiefly through their influence on the gastro-intestinal system and other organs. The influence of mechanical irritation to joints is self-evident. He speaks briefly on various external physical agencies, such as extreme heat, cold, etc. Finally, he discusses the application of this theory to treatment of chronic joint disorder. [J. B. H.]

3. Battle has collected and studied all the cases reported at the London hospitals of severe internal abdominal injuries. The total number of cases is about 2,500. Of these 64% are simple contusion of the abdomen. His work is limited to a study of those cases without external wound, but with the internal organs affected. He discusses in detail the symptoms arising from such injuries according to the part of the abdomen struck or the organ injured. In one class of about 50% of all cases there is shock, vomiting, acute abdominal pain and rigidity; in a second group, comprising about 40% of all cases, the initial symptoms are slight, but after a few hours severe symptoms set in. A third small group gives only indefinite symptoms at first, with no vomiting or apparent shock, little pain, tenderness or rigidity, with a gradually rising pulse and development of severe symptoms. He discusses in detail the various symptoms, the methods of operation, and presents many illustrative cases. He describes cases of rupture of the bladder, spleen, liver, etc. He gives the details of many previously reported cases in tabular form.

4. Guthrie describes the etiology of the various forms

of hydrocephalus, internal, congenital internal, acquired internal, external or subdural. He discusses the anatomy and physiology of this condition as well as the morbid anatomy and pathology. He briefly describes the symptoms of this condition and its diagnosis by lumbar puncture. He discusses treatment under four headings: (1) Lumbar puncture, (2) puncture and drainage of the lateral ventricles, (3) drainage of the subarachnoid space and (4) drainage of the ventricles into the subdural space. [J. B. H.]

7. LOCHHEAD, J. *Résumé of Recent Literature on the Development of Intrathoracic Surgery.*

2. Miles describes his method of treating acute gonorrheal urethritis by the Bier method. He has used this in over three hundred cases and believes it far superior to treatment of injection, safer for the patient to carry out and possible to use in cases of phimosis. The great objection is that it occupies an entire hour every day.

3. Greig discusses Volkmann's ischemic paralysis and gives the details of two interesting cases with photographs. [J. B. H.]

3. Addis, using a modification of McGowan's method of taking the blood coagulation time, concludes that, in spite of extreme morphological, physical and chemical alteration in the blood, the coagulation time may remain normal. In bacterial diseases no marked changes in coagulation time are seen unless the organisms are actually in the blood itself. When this occurs, the typhoid bacillus and the pneumococcus hasten coagulation, while streptoand staphylococci delay it. Moderate loss of blood has no effect on coagulability, but very large hemorrhages hasten it. [J. B. H.]

4. At one time it was thought impossible to show the appendix in an x-ray picture. Recently, however, it has been demonstrated that the appendix may be shown in certain cases. Bismuth is used in these examinations. As a result of observations on a case, Liertz concludes that the position of the appendix is the all-important factor in inflammations of it. The bacteria play entirely a secondary rôle, and the severity depends upon their virulence.

5. Grau reviews briefly some of the literature on blood clotting and the use of gelatin. Then he gives briefly the results of his tests. The method used for determining the clotting time is that suggested by Bürker. His conclusions are that gelatin in a large proportion of the cases calls forth a long-continued increase in the ability to clot. The cases in which gelatin should be used will be more clearly indicated when the mechanism by which gelatin aids clotting is more clearly demonstrated. [C. F., JR.]

1. The author describes Ehrlich's early experiments in treating syphilitic apes with various drugs, and of his success with dioxydiamido-arsenobenzol. This drug is commonly spoken of as "Preparation 606."

Last March, at Ehrlich's request, Wechselmann began to put this to a practical test in the treatment of human syphilis. He reports his results from a series of some 80 cases. He states that the most sceptic critic can no longer doubt that this new drug has a rapid and fundamental action on the symptoms of syphilis. Wechselmann illustrated this paper before the Medical Society of Berlin with numerous patients treated by him to prove his statements; these patients are briefly described in this paper. Then follows a full description of seven cases either apparently cured or improving rapidly under treatment. In many of these cases treatment with mercury and KI had not been able, even in the hands of experts, to check the progress of the disease. The results obtained from the use of this drug are evident in some cases after a few hours, and great improvement, if not a complete cure, follows in the course of a couple of weeks.

Following the injection of this drug there is usually a sharp rise in temperature, and often pain so severe in character that morphine has to be used, but these symptoms only last a short time. The patient almost immediately feels better and stronger in spite of the pain, the lesions decrease in size or disappear and the patient begins to gain in weight. One patient gained about 18 lb. in the three weeks following the injection of "Preparation 606."

Much seems to depend on the size of the dose used. The author has found that 0.45 gm. for women and 0.6 gm. for men gives the most certain results. Where the dose is too small, and the symptoms are not entirely relieved, a second dose must be given.

The author points out that it is too soon to say positively that the cures are permanent, but the evidence in hand certainly points to that as a probability.

As to the danger of the drug, animal experimentation seems to show that the tissues can withstand many times the dose given to obtain satisfactory results. It certainly has had no bad effects on the heart, kidneys or gastrointestinal canal so far as can be observed in the cases

already treated. A pregnant woman and a patient with nephritis have been treated for syphilis with this drug with no evil resulting. One fatality is noted in a syphilitic patient with pernicious anemia. [But as the patient was in a very low condition, with a hemoglobin of only 20% and as death followed eight days after administering the drug, it can hardly be regarded as due to the drug.] Careful examinations seem to show that this drug has no injurious effects on the optic nerve. The drug is used intramuscularly, and the author carefully describes his technic.

[The full discussion of this paper and Ehrlich's own remarks will be found on page 1292, No. 27, of the *Berliner Klinische Wochenschrift*.] [J. L. H.]

14. Interested in the possibility of cutting away a portion of mesentery in cases where that structure was involved by carcinoma, Von Haberer performed upon a series of dogs the experiment of ligating mesenteric arteries and stripping a portion of the gut of its mesentery. In some cases he wrapped the denuded portion in omentum, in others he did not. He concludes that because of anatomical differences, the results of such experiments upon dogs are not applicable to operations upon man. Dog's intestine, when stripped of its mesentery for a distance of from 10 to 30 cm., practically always becomes gangrenous before collateral circulation through the omentum can be established. In the few cases in which such circulation is established, ulceration of the gut and stenosis follow.

16. Kümmell's article is a lengthy discussion of appendicitis from several points of view. He believes the disease to be a sort of end-process following some systemic disturbance, such as influenza or colds. In support of this he presents figures which show that the disease is more than twice as prevalent in December as in the preceding or following months. The most important diagnostic point he thinks is the tenderness on deep pressure over the appendix. For showing the immediate condition of the appendix, and for predicting the future course of the attack, the white count is of little value; considerable information as to the amount of involvement of the peritoneum is gained by measuring the viscosity of the blood. Normal viscosity is four or five times that of distilled water. An increased viscosity denotes peritoneal inflammation. His figures of mortality in Germany are interesting. More deaths between the ages of ten and twenty-five occur from appendicitis than from all other diseases put together! For the past three years, the statistics of his clinic are as follows: Of 347 cases operated upon within the first forty-eight hours after the commencement of the attack, .5% died; of 481 cases operated upon between attacks, .2% died; of 108 cases with peritonitis, 23% died; of 31 cases with abscess, 16% died.

To the question, "How can we lower the mortality of appendicitis," his answer is "By early operation." Some cases with tenderness and occasional pain as their only symptom may be allowed to wait; all others should be operated upon as soon as the diagnosis is established. This should be within twenty-four hours in every case. The public, he says, has more sympathy with the doctor's desire to operate than with his procrastination.

19. Codivilla says that in the treatment of false joints and separations in the shafts of long bones, the two factors to be considered are the mechanical conditions of the part and its state of osteoplastic activity. The simpler methods, such as freshening the ends of fragments and wiring them, he passes over, but discusses more fully the method of treatment by transplantation of a bone flap. He lays down three rules: (*a*) The transplanted flap must be strong enough to withstand the pull of neighboring muscles, and large enough to permit of certain fixation with each of the fragments between which it is placed; (*b*) the slightest sepsis is fatal to success; (*c*) the limb must be supported by a dressing until such time as the transplanted bone is replaced by new growth. There are two kinds of bone flaps; the one is from a nearby bone (as from ulna to radius) with its pedicle intact; the other is a completely transplanted piece of bone from another part of the body. The former method is surer, but the latter is better where, because of injury or atrophy, the neighboring bone is likely to lack in vitality. The flap in either case must be well covered with periosteum and is bound into place by a metal suture at each end. [G. G. S.]

Obituary.

CHARLES JEWETT, M.D.

DR. CHARLES JEWETT, the most eminent obstetrical authority in Brooklyn, N. Y., died suddenly at his residence in that borough on Aug. 6. He was seventy years of age, and was graduated from the College of Physicians and Surgeons, New York, in 1871. For many years he was professor of obstetrics in the Long Island College Hospital, Brooklyn, and his services were largely in demand in consultation. His contributions to society proceedings and to medical literature were also most highly valued. During his professional career he held many hospital appointments, and at the time of his death he was surgeon to the Long Island College Hospital, consulting obstetrician to the King's County Hospital, consulting surgeon to St. Christopher's Hospital, and consulting gynecologist to the Bushwick, Swedish and German Hospitals and the Bushwick and Eastern District Dispensaries. In addition to membership in a large number of local and national medical societies, Dr. Jewett was a member of the British Gynecological Society and the International Congress of Obstetricians and Gynecologists.

Correspondence.

PARIS LETTER.

A NOVEL CURE FOR DIABETES.

[From Our Special Correspondent.]

PARIS, July 15, 1910.

Mr. Editor: It is held by some that medicine has advanced from the rank of an art to that of a science. But in spite of this assertion we seem still to have great difficulty in coming to an agreement on even fundamental facts.

Take, for instance, the artificial emptying and cleansing of the large intestine by means of purgation and enemas. This is a device that has been in use for thousands of years. Ever since anything has been known of medicine by record, certainly from Hippocrates downwards, and

most probably also among the Egyptians, have these therapeutic agencies been resorted to; and yet at the present day different authorities and different races hold views on the question that are totally opposed to each other.

Only last year, a physician of some standing in this city, Burlureaux, came out with a book entitled, "Un Danger Social — la Purgation"; on the other hand, another physician, belonging to the same scientific society has just published a book of three hundred pages, to be referred to at length farther on, — a Dr. Guelpa, — in which regular courses of severe purgation, combined with absolute fasting, nothing but water being allowed, are proved as a species of *fons juventutis*, besides being a means of curing various chronic disorders and among others, diabetes. Yet you would think that during all these centuries humanity has had opportunity enough to decide which of these two extreme opinions is the correct one.

Now take the question of races. The French have apparently always had a fondness for the artificial evacuation of the large intestine. Is it necessary to refer to the immortal Rabelais, or to Molière's comedies, to prove this point, as regards days gone by? Do you happen to have read the records kept by the three successive physicians to Louis XIV, whereby it appears that this long-suffering monarch was purged upwards of two thousand times, not to speak of enemas without number?

Louis XIII was purged 259 times in one year and bled 47 times; while during the next six months 220 enemas were administered to his devoted rectum. The mémoirs of the day show, as well, that these three means constituted practically the entire medical science of the time, and whether you had smallpox, syphilis, gonorrhea, pneumonia, inflammatory rheumatism, asthma, an accident or a wound, — whatever the variety of your complaint was, your treatment was certain and never varied. Montaigue, Madame de Sérigné and her daughter, Marie de Médicis, Cardinal de Richelieu, were all purged, repurged and purged over again *ad infinitum!* In fact, if the seventeenth century did not already bear the appelation of the *Siècle du grand roi*," it could very well be referred to as the period of the apothesis of the purge and of the enema. A very interesting thesis was presented last year to the faculty of Paris by G. Berthe (No. 179) entitled, "Historique de la Purgation," in which these facts are all related at length, and what has been termed the "*esprit ganlois*" deals in the main with this department of medicine. That this "*esprit ganlois*" is not yet extinct can perhaps be illustrated by a short play I witnessed recently at one of the well-known boulevard theaters, where one of Paris' favorite and prettiest actresses flourished about the stage for upwards of an hour with a pail supposed to be full of bedroom slops in her hand, while her partner juggled with a porcelain *vase-de-nuit*, to the entire delectation of the audience.

At the present time even among the best physicians here the purge and enema hold a preponderating place, while among the ordinary people to purge oneself occupies at least as important a position in domestic economy as to take a bath, — if anything probably a more important one. And to give you an idea of the prominent position that the question has held in French literature I can refer to the bibliography at the end of Berthe's thesis, which covers *thirty-six* printed pages!

On the other hand, in our own country I should say that purges and enemas, the latter in particular, hold a most subordinate rôle. In France, for instance, it is not at all an unusual thing among the common people to hear a woman say: "Oh, I'm to have a day off, on Saturday; I shall take advantage of it to purge myself," — just as though it were some enjoyable event to which she had been looking forward, — a sort of Sunday in the country. But I should think that this is something that would practically never occur with us, where people only resort to such measures when in trouble and under immediate medical advice.

In fact, living in France but moving mainly among my own people, I have been led to make a comparison that is not without its humorous side. The antipathy of the French for a bath is proverbial. When I first came to Paris very few houses had bathrooms; on the rare occasions where a bath was taken it was ordered in from one of the establishments *ad hoc* that used to exist all over town. It seems to me that bathrooms now existing in all of the better class new houses are the direct outcome of the demand for them on the part of the great foreign population that lives in this city. Among the most amusing scenes that I have witnessed in my medical career here have been those where a robust French peasant woman, introduced into an American family in the capacity of wetnurse, has been called on to take a bath and scrub and clean. Many of these women never took a bath in their lives.

The American, on the other hand, seems to me to be possessed of a bath mania. They are at it all day long, especially in certain classes, where two or three baths a day would not appear in the least out of the way. In a large hotel put up recently in the Champs Élysées for traveling Americans I was in a small suite the other day which comprised two bedrooms, one double and one single. For these two rooms were supplied *three* fine bathrooms, the two occupants of the double room not being able apparently to put up with a single bathroom. Whether the human skin was ever intended to stand this sort of discipline is a point on which my mind is not at all made up.

So this is the comparison I have arrived at between the two races. They both have a standard of cleanliness, but these standards are altogether different. A Frenchwoman, for instance, might take a cold enema every morning, and a purge from time to time, but would seldom bathe and would cover her face with lard and powder. Her American sister on the other hand, would only attend to her intestine under compulsion and medical orders, would shun lard and powder, but would spend a certain part of her existence, not immaterial, in her bathtub with hot water and soap. In short, it all comes to this: These people seem to concentrate on the endoderm, and let the ektoderm take care of itself; our people just the reverse, — *et voilà tout.*

Whether there is not a large part of truth in the French habit of clearing out the lower bowel at intervals is a point that can certainly be maintained. The waste-eliminating apparatus of the body provided with receptacles and closed orifices (intestinal, urinary) are admirable devices and work beautifully so long as the flow of the contents is regular and free and there is no delay or obstruction; when once the latter occurs, troubles begin, *vide* prostatic enlargement. Now one of the commonest ailments of our day, if not the commonest, is faulty elaboration and sluggish elimination of waste, due to our rich food, over-eating, and the artificiality of civilized life. What can you expect of an intestine that is treated as follows: I will cite two cases I have personally met. One woman, accustomed to every American luxury, went to Dieppe. Now Dieppe is quite an important seaside resort three and a half hours from Paris and has good hotels. But the dame in question found the sanitary apparatus supplied so far short of her own luxurious w. c., that after sticking it out for four days she took the train back to Paris to have an action! The other woman has built herself an arrangement for these matters in her house here that must be almost unique; and so spoiled is she that she laments that when she wants to leave town in the summer for a change, there are only three places *in Europe* where she can go to get the comfort she requires in these details!

From intestinal stagnation we now think arise a large number of the ills to which the flesh is heir, — v. Metchnikoff, etc., etc. Does it then seem illogical that since this condition is apparently inseparable from modern civilized life, the French should attach so much importance to its artificial relief? Possibly if the two races would each take something from the other they would mutually gain; if instead of concentrating on one coating and neglecting the other, they paid a moderate amount of attention *to both*, it would be more advisable. Is it an exaggeration to affirm that two out of three American women have chronic intestinal sluggishness and retention? There is a great deal more to be said on this question, but I must hasten on to Guelpa's book.

Guelpa is the man I referred to above, who has come as a twentieth century apostle of the purgatives. His opinion is categorical, and there is no beating about the bush: "purgation, well-understood and handled, is the most powerful, certain and frequently indicated means in the fight against disease and for the preservation of health."

Again: "Purgation is perhaps the most active means that nature has placed at our disposal to preserve good health and secure a favorable outcome in disease."

This interesting little book deals with two main points: One the manner in which the human system can be periodically rejuvenated by a three-day course of purgation and water diet; the other the extraordinary result that can be procured in an ordinary case of diabetes by the same practice. That Guelpa's views are not mere theory will be seen in the fact that he claims to have put himself through these purge-water fasting courses not less than fifty times, and for periods ranging from one to seven days, and has treated a large number of patients in the same manner, including nineteen cases of diabetes, with almost unfailing favorable results.

His plan is based on Dusjardin-Beaumetz and Stackler's recovery that in typhoid fever recovery is regular and rapid in direct proportion to the patient's loss in weight; that when this weight remains stationary, the fever is certain to be high; that when the loss in weight is not in proportion to the intensity of the pyrexin, the disease is always more serious and prolonged and the convalescence more difficult. These ideas Guelpa has found applicable to all febrile disorders, and he accounts for the fact in the following manner. The system is clogged and hampered by a mass of fluids, cells, old and decaying tissues, which it must get rid of in order that the disease may disappear; the quicker this end is accomplished the sooner perfect health is restored, — health even better than before the illness. It is perhaps interesting in this connection to note that it is not uncommon to hear a patient remark that after an attack of typhoid fever he felt better than for years previously!

His method then amounts in short to a vigorous spring cleaning of the economy, the only original point being the addition of the energetic and repeated purge to the fast and water diet often recommended for shorter periods by medical men, and, strangely enough, by the Church of Rome!

Guelpa thinks that in order to accomplish something worth having the diet ought to be maintained for at least three times twenty-four hours, though he himself has often gone for longer periods. Thus, during the discussion that was held on this subject before the Society of Therapeutics he on one occasion appeared before the members on the *seventh day* of one of his treatments, during which he had purged himself vigorously four times and taken nothing beyond four or five cups of an infusion of tea or coffee per diem. During that period he claimed that he had been able to work with the greatest ease until very late at night, and was again up and about by seven in the morning. He then informed his colleagues that the course he had just put himself through would place him in better health and enable him to do better intellectual work for several months to come.

On another occasion Guelpa made the journey from Tangiers to Paris (Thursday evening to Tuesday noon, — nearly five days) in very hot weather, on the following diet: Two purges, four cups of tea, four lemonades, two cups of coffee and a bottle of water; and so excellent was his condition on arriving in Paris Tuesday that after a bath he attended to his practice all the morning and did not take a meal until noon!

His course is as follows:

1. In two, three or four days take a bottle of Hunyadi János water heated each A.M.; or, 40 to 50 gm. ol. ric. (upwards of four tablespoonfuls) to be followed by a liter of herb infusion.
2. No food whatever during the treatment.
3. Drink ad libitum, Evian water, boiled water, or any herb infusion.

The curious part of the affair is that he claims that this purgation is a *sine qua son;* that it does away entirely with the sensation of hunger, which, he states, is not the outcry of the outraged system for food, but is due to the accumulation of waste-products and toxic materials eliminated into the intestinal canal demanding to be swept away! That *this* theory was not unanimously accepted by his colleagues, you can well understand.

He takes his hot bottle of Hunyadi at a single dose. Personally he gives it to himself through a stomach tube, and follows it up with something to remove the taste. He thinks that salts are far better than the other purges, and that they must be taken well diluted, otherwise they give rise to thirst. A powerful dose is necessary; it will act in a short time, producing two or three motions, whereas a smaller dose never gets through, but stirs up things in general and makes you uncomfortable throughout the day. The first day is the only disagreeable one; once the first big purge has acted, the sensation of hunger disappears and will not return if the purge is renewed each A.M.

The outcome of the course is a loss in weight of about 2½ lb. per diem, and the origin of Guelpa's enthusiasm for the method was his auto-observation, given at length, page 214.[1] After a succession of attacks of grippe he had been left in a condition of neurasthenia with increase in weight (22 lb.) that rendered reading, thinking and literary work next to impossible. One of these courses produced such marked improvement that he repeated it twice again at brief intervals, reducing his weight by 20 lb. and recovering all of his former mental energy and application to work.

The clinical side of the question is the application of this system to diabetes where Guelpa claims to have obtained over and over again the relief of most alarming conditions, in diabetic patients, and furthermore, the total disappearance of glucose in more ordinary cases. It is furthermore claimed in all seriousness that if the cure is repeated at proper intervals and the patient will follow a strict and sober régime in the meantime, *the sugar does not reappear!* Guelpa distinctly speaks of "lasting spinal cures in diabetes."

This naturally struck the Therapeutic Society as rather a large order, and Bardet immediately proceeded to Albert Robin's ward at Beaujon and put the system to what may fairly be called a crucial test. He took a patient of a serious type, long standing, with a loss of flesh, 12 liters of urine per diem and 760 gm. of sugar, — say a pound and a half. In twenty-four hours of water diet, without purgation, the urine fell to 2 liters and the sugar to 13 gm., and in forty-eight hours, the urine was 600 gm. and the sugar *zero!* So Bardet came back to the society, reported the case, and admitted that here was a factor that was altogether new and that would have to be studied. In the space at my disposal I shall not be able to cite the many case-histories in Guelpa's book; but after reading them it is impossible not to agree with Bardet that we have here something quite unknown and that is well worth our closest attention, — for instance, what will be the action of this treatment on such serious incidents as diabetic coma and diabetic gangrene, where we are practically disarmed at present?

It has seemed to me, in closing, that the final clause of Bardet's paper on this subject would well bear translation. It can hardly be called new, but the idea is always worth repeating: "Once again we are led to observe the strong influence exerted by excessive digestion over our physiologic reactions. In the state of nature, animals are rarely dyspeptic; and nutritive disorders which are the sad privilege of man, are almost unknown to them. It is indeed a melancholy fact that the brain development of the human animal, which in certain respects has produced admirable results, has unfortunately chiefly resulted in leading him to eat without hunger, to drink without thirst and to indulge in sexual intercourse at all hours, — all to help to ruin his system and shorten his days, for there is not the slightest doubt these three factors are the true origin of the chronic disorders that decimate the race."

Was ever a true saying better expressed?

"*S.*"

LICHFIELD AND ITS MEDICAL TRADITIONS.

[*From our foreign correspondent.*]

Lichfield, July 16, 1910.

Mr. Editor: When Johnson said of the inhabitants of Lichfield that they were "the most sober, decent people in England, the genteelest in proportion to their wealth, and spoke the purest English," he was not far amiss, though one is tempted to believe that his remark was prompted more by local pride than by unbiased judgment.

[1] Auto-intoxication et désintoxication, Doin, 1910.

For to-day the people of Lichfield seem particularly thrifty, intelligent, and contented, and their speech more like our own than one finds even in London or in many of the peripheral counties.

The town itself is situated in the pleasant valley of the "sunny and silver Trent," in the broad, fertile, inland district that has been called the heart of England. Architecturally, it is dominated by the cathedral, whose three beautiful spires, "the three ladies of the vale," — are mirrored in the unrippled surface of the minster pool, and whose row of stately old lindens shade the dean's walk and fill the close with the perfume of their blossoms. Historically the interest of Lichfield centers about Samuel Johnson, to whose birthplace all the street-signs point. The house, now in perpetual care, is open to the public, and contains many memorabilia of the great lexicographer. From the windows of the birth-room, or of the shop below, in which Samuel's father Michael sold books, one can look out on the cobble-paved marketplace at the statue of Dr. Samuel and beyond at that of his conceited, officious biographer, Boswell. It is interesting to conjecture whether Johnson ever dreamed, when as a barefoot boy in that market-place he was hooted at by his fellows for his ungainliness, that some day he should lie in Westminster Abbey while his monument and home in his native town should be a visiting-place for scores of literary pilgrims.

"Seven cities fought for Homer dead,
Through which the living Homer begg'd his bread."

Apart from Johnson and the minster, however, Lichfield is not devoid of other interests. Here for many years in a house hard by the cathedral, lived Erasmus Darwin, doctor of medicine, grandfather of Charles Darwin, who perhaps did more than any other man in his century to modify the scientific and religious thought of the future. Here, too, as dean of the cathedral, lived and died Launcelot Addison, father of the famous essayist. There is a tablet in the cathedral to Dean Launcelot and the more illustrious Joseph, and on the opposite side of the nave one to that "amiable, virtuous and distiguished" personage, — though perhaps readers of Pope would incline to dissent from the appropriateness of the adjectives, — Lady Mary Wortley Montague, "who happily introduced from Turkey into this Country the Salutary Art of inoculating the Small-Pox. Convinced of its Efficacy she first tried it with Success on her own Children, and then recommended the Practise of it to her fellow-Citizens. Thus by her Example and Advice we have softened the Virulence and escaped the danger of this Malignant Disease." Whatever the virtues or failings of Lady Mary, and whether or no she "robb'd the whole tree" of knowledge, she surely applied some of its fruits for the benefit of mankind; and in these days of anti-vaccination agitation it is pleasant, though perhaps mortifying, to find that these benefits were appreciated by an age that had not yet outgrown the vivid terror of epidemic smallpox.

Medically, Lichfield to-day seems well provided for in proportion to its population of approximately 10,000. Near the center of the town is the Victoria Nursing Home, a hospital of fourteen beds for both medical (non-contagious) and surgical cases, with a daily out-patient clinic, and provision for receiving and treating accidents or emergencies at any time. It is administered by a lady superintendent, under the direction of a visiting staff of local physicians and surgeons. There are also an infirmary for incurables, and a small maternity home, all open free to the poor. The term "home," or "infirmary" is used here apparently in distinction from the word "hospital," which means really an almshouse, like the celebrated Leicester Hospital at Warwick, where the aged and indigent are cared for upon a public foundation. There are two such hospitals in Lichfield, at opposite ends of the town, both of ancient establishment and endowment, one for "thirteen old poor men," the other for fifteen women. For some reason which does not appear, the former building is about twice the size of the latter, a fact which might be cited by the suffragettes as an ancient example of unjust sex discrimination.

To the east of Lichfield, by Stowe pool, stands the very old parish church of St. Chad, the patron saint of the town, who first brought Christianity among the inhabitants of this region. Near this church is St. Chad's well, now roofed over by a stone hut, and shown with great reverence as the spot where the good saint baptized the first Christians. Its waters are still and deep, but thick with green scum, and close to the churchyard.

"Where heaves the turf in many a mouldering heap," and the poor old woman who ran out with a dirty tumbler from the hut across the lane could not understand how we could refuse to taste the draught which she proffered and derive the benefit of its sacred properties. However, twopence consoled her, and she went back voluble in praise of the well, and probably happy, if not fortunate, in her ignorance of the bacillus of Eberth and of the reeking bacteria of decomposition. We preferred to walk home through hedge-bordered lanes across the meadows, and watch the swan sailing above her reflection in the pool, and listen to the minster bells chiming out of the gathering dusk, and smell again the faint perfume that lingered on the evening air till twilight slowly darkened into night.

MEDICUS PEREGRINUS.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JULY 23, 1910.

RECENT DEATHS.

DR. SILAS S. CARTWRIGHT, of Roxbury, Delaware County, N. Y., died on July 31, at the age of seventy-seven years. He was graduated from the College of Physicians and Surgeons, New York, in 1853, and served as a surgeon during the Civil War. In 1884 and 1885 he was a member of the State Legislature. He retired from practice in 1907, and for some time had been postmaster of Roxbury.

DR. HENRY F. KOESTER, of New York, died on Aug. 7, at the age of forty-seven years. He was born and received his preliminary education in Germany. He was graduated from Bellevue Hospital Medical College, New York, in 1891, and for some time was a medical inspector in the Health Department and attending physician to the Willard Parker, Kingston Avenue, and Riverside Hospitals, belonging to the department.

DR. WILLIAM G. PERRY, of Exeter, N. H., who has recently died, had passed his eighty-ninth birthday. His father, Dr. William Perry, dying in 1907, at ninety-eight years, had for a period of four years been Harvard's oldest graduate. Dr. Perry was graduated from Dartmouth College and from the New York College of Physicians and Surgeons, and after a period of professional study abroad opened an office in 1847 in his institution where he quickly established a large practice. He remained at Exeter throughout his long and active life.

WHAT IS THE EXPERIMENTAL BASIS FOR VACCINE THERAPY?*

BY THEOBALD SMITH, M.D., JAMAICA PLAIN.

THE historical development of the use of vaccines as defences in the struggle of man against infectious diseases may be considered as fairly well known. The observation made in early stages of civilization that one attack protects more or less securely against a following attack led the way to the practice of inducing mild cases by exposure and inoculation to prevent more severe ones later. Smallpox inoculation, practiced up to the beginning of the nineteenth century, gave way to cow-pox as a safer and easier way of acquiring immunity against smallpox. The many-sided life work of Pasteur was, in his later years, limited almost wholly to the practical application of the biological law that a mild attack of an infectious disease usually protects against a subsequent one. He devoted most of his time to the working out of methods of reducing the virulence of animal-disease germs so that they might safely be used to produce a mild type of disease which was to fortify the animal when continually surrounded by infection later on.

In 1885 Pasteur introduced a new idea in the use of antirabic vaccination after infection. The immunity was to be rapidly induced after the human being had been bitten by a rabid animal, not before. In 1890 Koch presented to the world his tuberculin as an aid in the cure of tuberculosis. Though at first misunderstood, the action of tuberculin is essentially protective or immunizing rather than curative.

In 1902 A. E. Wright took still another step in advance in advocating the inoculation of dead bacteria in various chronic affections due to these bacteria. So far as I am informed, Wright at first limited the application of his vaccines to chronic infections with well-marked and usually external localization of the infectious processes.

Very recently the practice of injecting dead bacteria has been extended to more acute diseases like typhoid, even to a disease of such relatively short duration as pneumonia, and to infections in which a general systemic intoxication and even bacteriemia exists.

This very brief sketch is significant in showing us the rapid march of events from vaccination before exposure to protect from any impending infection, to vaccination after exposure and even during the course of an acute disease.

Knowing how difficult it usually is to prove the efficacy of any therapeutic method, owing to the fact that cases of disease, even those complicated with infectious organisms, are individualized and, therefore, not comparable, we naturally ask the question whether there are many demonstrated guiding principles derived from laboratory and allied experimental work to assist us in estimating the value of vaccine therapy. The statistical method so often invoked in clinical medicine is slow and dependent upon the accuracy with which all case details have been worked out and classified.

At the outset I may state that experimental medicine has very little to offer us which is of service in deciding upon the efficacy or harmfulness of vaccination during disease. The practicing physician in co-operation with the clinical laboratory will have to work out his own salvation, and this can be done only with the aid of the most rigorous and painstaking methods which medical science can supply. Any other course is certain to lead astray.

In view of this situation I have very little of value to contribute to the discussion. There are, however, a few aspects which, though familiar, should not be lost sight of, and I shall briefly review these so far as they are the product of experiment rather than of observation.

Vaccine therapy or therapeutic vaccination is simply an offshoot of prophylactic vaccination. One shades insensibly into the other. The boundaries between what we call health and disease are clinically undefinable. In health we may harbor disease germs and we may be slightly infected without being aware of it. The principles underlying prophylactic vaccination are thus applicable to vaccine therapy.

Concerning the capacity of the individual to be protected by vaccination, at least for a time, against infectious diseases, there is no longer any reasonable doubt. All attacks of infectious disease, either artificial through vaccination, or spontaneous, lead to an immunity of longer or shorter duration. The occasional statement that certain infections predispose the individual to subsequent attacks may be true clinically, but the predisposing factor in such diseases will probably in all cases be found to be of a mechanical or physiological nature which interferes with the acquired immunity. The underlying generalization that all infectious diseases tend to raise the level of immunity of the individual after recovery is not invalidated by these apparent exceptions. Experimental medicine has supplied us with a large stock of information on this phase of the subject. The study of the great plagues of animal life and the suppression of them by vaccination has furnished the experimental basis for human preventive inoculation. Unfortunately, the most effective methods devised to protect animals cannot be safely used on the human subject, because they are too heroic and might, occasionally, jeopardize life. Our methods must be so toned down as to fit the weakest and most susceptible. In animal life this is not necessary, for it is desirable that the weakest be eliminated and that it shall not propagate its kind.

Experiments on animals have taught us that immunity and susceptibility are purely relative terms. They are matters of more or less. Frequently these terms are used as if they meant respectively the presence and absence of something which might be represented by the signs + and —. These latter conceptions are erroneous, for an immune animal simply possesses something more

* Read before The Massachusetts Medical Society, June 8, 1910.

than a susceptible one, or perhaps a greater capacity for acquiring something more. Hence when we induce immunity it is simply to stimulate the body to a higher level of resistance to any given infection rather than to put into it something that was never there before.

Man possesses already a high degree of immunity towards most infectious diseases, for after exposure not all individuals are attacked, and even under unfavorable conditions only a small percentage succumb. A complete absence of immunity would signify that all exposed would contract a given disease and die. How far we are from any such situation is a matter of daily experience in medical practice.

When immunity is induced artificially, it is raised by degrees. The animal that perhaps would have died very quickly without vaccination dies after a longer struggle. The one that might have succumbed to a chronic disease passes through a mild attack and recovers. Lastly, the one which would have had a mild attack does not become ill at all. It may be demonstrated experimentally that an animal made immune to a given fatal dose of bacteria inoculated into the subcutis is still susceptible when the same dose is injected into a serous cavity such as the peritoneal cavity, and least immune when the bacteria are introduced directly into the blood stream.

By repeated vaccination the animal which would have died of an acute septicemic attack may become so highly immune as to be completely protected against illness after exposure or inoculation of a fatal dose. This is not always possible, however, for the capacity of the animal to produce enough immune bodies may be limited individually as well as specifically, and no amount of treatment might avail in some cases.

By inducing immunity the type of disease may also be changed. In place of the septicemic type, the blood infection disappears and the virus becomes localized on serous membranes, in joints or in certain organs or in the subcutis and skin. The more localized the process, the higher the general immunity, which, as it were, crowds the invader into a corner. These modifications are producible at will in the laboratory, and are no longer matters of dispute. A localized infection, from the experimental point of view, may thus mean one of two things. Either the individual possesses already a relatively high degree of resistance, or else the micro-organism is of such a low order of virulence that it makes no headway against an average resistance.

Immunity is more easily acquired or raised towards certain micro-organisms than towards others. Thus it is relatively easy to protect against smallpox, but I doubt that complete protection against tuberculosis would be easy. This difference is inherent in the physiology and chemistry of the bacterial cell. On the other hand, certain individuals are more easily protected against infectious diseases by vaccination than others, probably because they start on a higher level. Let me illustrate. Certain individuals contract hemorrhagic types of infectious diseases — smallpox, for example — and die early in the disease. This means usually great susceptibility rather than a high degree of virulence, because such cases are rare among types of ordinary severity in the same outbreak. Now if we should vaccinate such a person, what would be the result? In the absence of any possibility to find out by actual trial, I venture to assume that such a person's immunity would be raised by ordinary vaccination only enough to escape the fatal disease. He would probably contract varioloid after exposure. In estimating the success of vaccination, we often blame the vaccine for failures without taking into consideration the very low resistance of certain individuals. In the laboratory, a small percentage of the animals used show a distinctly higher or lower capacity for immunization than the rest.

Another factor which must not be lost sight of is that of time in producing immunity. The rousing of protective machinery cannot be hurried. Each disease has its normal periods of incubation, of fever and of convalescence, to which there are, indeed, exceptions due to intercurrent causes. These periods are functions of sensitizing and immunizing processes. The so-called accelerated reactions brought out by repeated injections of tuberculin and repeated application of vaccine are due not to any greater promptness in the production of antibodies, but rather in their release or discharge, or else due to the interaction of vaccines with immune bodies already formed.

I have several times used the word "antibodies" as factors in immunity. It is well known that while the practical work of testing the efficiency of vaccines on man and animals has been going on in a more or less empirical, tentative manner, the analysis of the phenomena of infection and recovery has been going on in many laboratories, thanks to the impetus given by the discovery of antitoxin and by the establishment of laboratories supported by state and national resources.

Immunity has been shown to consist of a series of co-operating and interacting forces represented by antitoxins, bacteriolysins, opsonins, agglutinins and phagocytosis. The precise machinery which comes into play for any given micro-organism or any given species of animal is probably not identical with that in use for any other micro-organism or by any other host species. A complete explanation for the immunity which suppresses the invasion of any given organism, such as the plague or the tubercle bacillus, is not known. We know only details and fragments not easily pieced together. The discovery of the different antibodies has not thus far been of much assistance in practically gauging the value of vaccines or making them more effective, if we except the measurement of the opsonic index as devised by A. E. Wright. The various antibodies however, have been of very great service in diagnosis, and each one has now been harnessed to certain special methods of recognizing specific diseases, blood, toxins, animal foods, etc.

Another point of great importance is the temporary loss of protective substances, i. e., the lowering of the immunity level caused both by the disease and by vaccination. The lowering of the opsonic index after the injection of vaccines, of the antitoxic value of the blood in horses after injection of large doses of toxin, are illustrations of this condition. Each vaccination uses up some of the protective substances already present. It has been stated by several authors who have vaccinated calves against tuberculosis on a large scale that the treated animals are more predisposed to infection for a time after the injection of the vaccine.

Turning now to the application of vaccines where a diseased condition already exists, I have already stated that experimental medicine has not as yet cleared the way for a proper valuation of vaccine therapy. Few animal infections have been treated with vaccines. Only very few human diseases are transmissible to animals, and although much work has been done on small animals with such viruses as typhoid and cholera, these diseases are not contracted by animals spontaneously, and the results of experiments have only a limited application to human diseases, contracted in the natural way. Nor is there any encouraging outlook that in the near future experiment will take the place of bedside observation in this subject.

There are, however, a few theoretical considerations which may be of use in weighing the evidence for or against this kind of therapy.

At the beginning let us try to picture to ourselves, as clearly as our present knowledge will permit, the difference between prophylactic and therapeutic vaccination. If we inject into an animal once, twice or oftener a given dose of living or dead bacteria, we find that this animal is protected against a subsequent inoculation which would have been fatal to an untreated animal. The vaccination has put the body in a state of preparedness, probably by increasing the supply of suitable antibodies. The few invading bacteria are easily overcome, destroyed or else surrounded and gradually starved and asphyxiated. There is relatively little to do, and the prepared state of the body has made the task easy. Now, let us suppose that the body was not so well prepared; not so prompt in closing in upon the invaders. They then begin to multiply and when the body is roused a large number of bacteria are to be destroyed. A local process of inflammation and perhaps suppuration is the result. Suppose that the invasion extends beyond the place of entry, and the bacteria are carried some distance to establish many foci of multiplication. We have then a systemic infection. The process might have been nipped in the bud by vaccination or preparedness.

Now the success attending vaccinal prophylaxis has carried it as a practice into the heart of disease. The wholly different situation between vaccination during health and vaccination in disease has not, I presume, always impressed itself on the enthusiastic vaccinator. In the one case only a few bacteria are to be checked and disposed of; in the other myriads, with a body largely robbed of its store of antibodies. When we consider how difficult it is to protect the body against the future invasion of many diseases, it would seem almost hopeless to do anything with a similar procedure after such diseases have taken a good start. We are in danger of taking the ounce of prevention and using it as a pound of cure. This, it seems to me, is the situation as viewed from the experimental side. The presence of virulent living bacteria makes it seem absurd to add dead ones. Why is not the former stimulus enough?

In the case of chronic, localized affections in which vaccines have been much used, the justification for the use of vaccines is perhaps not so difficult as it seems. In the first place, the body already possesses a high degree of resistance, otherwise the process would not be localized and suppressed elsewhere. The infection is located, perhaps walled off in the disease foci with imperfect and interrupted relation with the fluid that eventually receives and redistributes all immune bodies, the blood. Again the bacteria themselves may have acquired enough immunity to the antibodies that reach them to resist lysis or phagocytosis. The process halts, immune bodies are no longer produced because the stimulus is lacking. The injected bacteria are now capable of raising the immunity of the body fluids, first by becoming themselves destroyed and furnishing the necessary stimulus, and second by arousing where the injection has been made, a larger territory of tissue to the production of antibodies. This bringing into play larger and larger areas of tissue I have used to explain certain phenomena in antitoxin immunity. If this view is correct, the continual change of the point of application of vaccines would greatly add to the productivity of the tissues in immune bodies.

The production of more antibodies by the tissues under the influence of vaccines leads to a disturbance of the established equilibrium between the bacteria and surrounding tissues in the local disease processes and to sufficient reaction to effect a cure. Where the capacity of the body for producing antibodies is low or exhausted, no cure can be hoped for. Surgical interference becomes here of the greatest value in opening up abscesses, incising indurated inflammatory foci, thereby giving freer access to the immune forces of the blood and causing auto-inoculation, i. e., the escape of bacteria and their products from the local process into the circulation and the establishment of other centers of antibody production.

The effectiveness of vaccines applied in the course of acute febrile diseases, such as typhoid fever and pneumonia, must be accounted for by principles of which experimental medicine has as yet no definite knowledge. The presence of fever is generally regarded as indicating bacterial activity with resulting toxemia. Theoretically no advantage can be expected from adding more toxins. Perhaps, according to the theory I advanced, by bringing into action more cell territories outside the organs and tissues immediately

affected, the disadvantages of the addition of toxin are outweighed by certain advantages.

The use of vaccines may be compatible with the existence of bacteria in the blood and internal organs whenever the infecting bacteria develop a high degree of parasitism with low degree of toxicity. Under such conditions the bacteria are immune against the existing forces, and the introduction, in vaccines, of bacteria more easily worked over by the body, may give the necessary impulse to a higher level of immunity. Or, the higher degree of parasitism may be associated with the usual toxicity, but owing to the fact that the bacteria are relatively immune, very little toxin is set free. Now, it might be interposed that under such conditions there is no reason why the blood should not sooner or later swarm with bacteria whose destruction would lead to dangerous toxemia when the immunity becomes raised by vaccination. To meet this objection another hypothesis would have to be interposed, one which has occupied my attention more particularly in tuberculosis. If the bacteria are well protected against destruction, they may at the same time be restricted, in multiplication, for their protecting envelopes or capsules may interfere with multiplication.

These suggestions indicate how complex the mutual relation between the tissues of the host and the parasite may be. It behooves us, therefore, to be exceedingly careful in the use of vaccines and not to lean too heavily on the repeated statements made that vaccines do no harm. They have introduced a truly experimental factor into clinical medicine and surgery, and no one should undertake their use in any but the superficial affections, who is unfamiliar with the principles of immunology and incapable of utilizing and exploiting all that is now well established experimentally concerning immunity and susceptibility. Each specific disease, each bacterial localization to be treated, must be considered a problem by itself, to which the experience gained in other types of infections may or may not be directly applicable. No vaccine should be administered simply because it produces an occasional drop in temperature and symptomatic improvement. Only the final outcome of the disease process should serve as a guide for subsequent cases.

DISCUSSION.

Dr. A. L. Chute, of Boston: My personal experience with vaccines has been limited practically to their use in suppurations in the genito-urinary tract.

These infections seem to fall naturally into three great groups, which, in order of frequency, are: The gonorrheal infections, the infections with the common pyogenic organisms and the infection with the tubercle bacillus.

It seems unwise at present to attempt to estimate the value of tuberculin in the treatment of tuberculosis of the urinary tract. The disease is often a very slow one, and perhaps sufficient time has not yet elapsed to allow us to draw accurate conclusions as to its value.

The infections of the urethra, prostate and epididymis with the gonococcus may be considered together. A considerable use of the gonococcus vaccines, both the autogenous and the stock, at the time when its use was first advocated, convinced me that it was powerless to influence the course of infections of this sort. In gonorrheal urethritis the intensity of the attack varies greatly as it also does in epididymitis and prostatitis. One sees cases in which the acute symptoms disappear under the use of vaccine, but as this is the usual course of the disease, this argues nothing for the efficacy of vaccines. In comparing, in the same clinic, a number of cases treated with vaccines, and a number treated with the usual methods by irrigation, my conclusion was that the vaccine treatment was not as effective as the older method; that it had no specific action. I think this is the conclusion that most men have reached regarding this method of treatment.

When one comes to the infections of the urinary tract with the common pyogenic organisms, the colon bacillus, staphylococcus, proteus, micrococcus ureæ, pyocyaneus, etc., one must consider the ordinary course of these infections in order to estimate the value of vaccines. The acute infections of this type tend to improve and to get well either without treatment or under very simple treatment, in cases where the drainage is efficient, that is, when the bladder and kidney pelves empty themsleves completely. When vaccines are used in such cases, their use in no way hinders the usual course of the disease and gives color to their apparent efficiency. The cases in which spontaneous recovery is not the rule are, for the most part, those in which there is poor drainage. I have treated a moderate number of such cases with autogenous vaccines, and have seen a much larger number. In none have I been able to see that the vaccine treatment produced any effect. The same thing applies to cases of bacteriuria.

At the meeting of the American Association of Genito-Urinary Surgeons in May of this year, this subject was taken up. O'Neil, who made a report on the status of vaccine treatment from a study of the literature, drew the conclusion that the use of vaccines in this class of cases was without effect. Geraghty, also, reported a number of cases of urinary infections with the various pyogenic organisms, in which he had followed up the vaccine treatment for a year or more, and in which the result was negative.

I feel that it remains to be proven that the use of vaccines affects in the slightest degree the natural course of infection of the urinary tract with pyogenic organisms. In such cases as I have tried them they have been unsuccessful. This method of treatment has also been unsuccessful in many cases that I have seen in which others have tried vaccines. Its successes, I believe, have been limited to the instances where it has been used in cases that would have gotten well without its use.

Dr. Timothy Leary, of Jamaica Plain, discussed Dr. Smith's paper, but did not care to have his remarks printed.

Dr. Lesley H. Spooner, of Boston: Dr. M. W. Richardson cannot be present and he has asked me to say just a few words on antityphoid vaccination. This subject I studied through Dr. Richardson's instigation six months ago, the investigation covering a period of six months at the Massachusetts General Hospital. The research was undertaken because of the relatively high morbidity of typhoid contracted in that institution, 2% of those exposed having developed the disease. The results were satisfactory in two ways: In the first place by the small doses of vaccine I was able to eliminate any constitutional reaction and reduce the local reaction to a minimum; in the second place, by producing Widal reactions in dilutions which compare very favorably with those produced by the disease itself. Lastly, I may state that no typhoid has been contracted

in the hospital within the last year. This is not absolutely conclusive, of course, but it is at least very encouraging.

From this work it seems to me that it may be concluded that typhoid vaccination should be utilized among those constantly exposed to the diseases, such as physicians and nurses. It should also be advised among those who are traveling abroad and, even more, through this country, where typhoid may be contracted easily, from water and milk supplies; and thirdly, that it may be encouraged in communities where typhoid is epidemic, also in families where a case is recognized early in the disease and where other members of the family have been exposed.

Other work has been done recently in America, and Major Russell, of the United States Army, has published an admirable report in the *Johns Hopkins Bulletin* of December, 1909, covering a very extensive work.

The salient facts which have been brought out in my own work are that I have been able to produce in a series of one hundred cases Widal reactions of such a high degree that they indicate an immunity against the disease by the use of small doses, frequently repeated. And that these small administrations of vaccine do not give rise to the violent constitutional reactions which have been so troublesome to the inoculated in England.

ON THE IMPORTANCE OF DETERMINING THE POTENCY OF DIGITALIS PREPARATIONS.*

BY JOSEPH H. PRATT, M.D., BOSTON.

(From the Department of the Theory and Practice of Physic and the Physiological Laboratory, Harvard University.)

No one can have read the case-reports in William Withering's "Account of the Foxglove and Some of its Medical Uses" [1] without having been struck with the remarkable efficacy of digitalis in his hands. It was Withering who discovered the diuretic properties of digitalis and introduced its use in the treatment of heart disease. His classical monograph is to-day, as it has been for over one hundred years, the best guide to the employment of digitalis. One hundred and sixty-three cases are described in which the drug was given under Withering's direction, and there are, in addition, notes on many cases communicated from correspondents. The entire work is a model of keen observation and sound reasoning, and one free from "any unjust predilection in favor of the medicine."

Digitalis, as Osler [2] says, is one of the dozen drugs the uses of which repay a lifelong study. There is truth in the German aphorism quoted by His [3] that the experienced physician can be distinguished from the inexperienced one by the way in which he uses digitalis.

The vital importance of having active preparations of this lifesaving drug does not need to be emphasized. Inert digitalis can be compared to a life preserver that will not float. The tragedies caused by the one in disasters at sea have been duplicated by the other in many a household.

Little attention has been paid by our physicians and pharmacists to the preservation of digitalis leaves, although excellent studies on the physiological standardization of digitalis and strophanthus preparations have been made in this country. (Houghton,[4] Famulener and Lyons,[5] Edmunds,[6] Hatcher,[7] Edmunds and Hale,[8] and Hale.[9], [10]) The statement is made in the last edition of the National Dispensatory (1909) [11] that there appears to be no foundation for the idea that the leaves deteriorate rapidly and are nearly or quite worthless after a year from the time of their collection.

Focke [12] has proved by biological tests that the presence of moisture in the leaves causes a rapid loss of the active principles. This is probably due to the action of ferments. Leaves which when dried contain 8% of moisture lost three fourths of their strength at the end of one year. On the other hand, leaves that were dried until they contained only 1.5% of moisture and then placed in airtight bottles lost practically none of their potency in a year. Focke asserts that improper drying of the leaf accounts for differences in strength amounting to 500% or more. Ziegenbein [13] has proved by physiological and chemical methods that the strength of the digitalis varies greatly with the locality in which it is grown. When the clinicians, Kussmaul, Naunyn and Krehl came to Strassburg as professors in the university, they each in turn discovered that the Alsacian digitalis was much stronger than that to which they had been accustomed and that it was necessary to use smaller doses in order to avoid marked toxic effects. Variation in the potency of digitalis obtained from apothecaries is due chiefly, as Focke says, to deterioration from age and moisture and not to the habitat of the plant. Focke,[14] in 1904, gave definite rules for the preparation and preservation of digitalis. The leaves should be dried as soon as gathered at a temperature below 100° C. After being well dried so that their water content is not more than 1.5%, they should be rubbed down to a powder while still exposed to a moderate heat. By the mixture of strong with weaker digitalis it is possible to obtain one of a standard strength as determined by the biological tests. The powdered leaf should be placed in narrow mouthed bottles not containing over 50 gm. Focke's method has been adopted by two firms, G. Schallmeyer, of Marburg, and Cæsar and Loretz, of Halle.

Recent scientific tests have shown that the drug is best preserved and administered in the form of powder. It is interesting to note that this was known to Withering. He gave the following definite directions for the preparation of the powder which differ in no essential from those of Focke. "The leaf-stalk and mid-rib of the leaves should be rejected, and the remaining part should be dried, either in the sunshine or on a tin pan or pewter dish before a fire. If well dried, they readily rub down to a beautiful green powder, which weighs something less than one fifth of the original weight of the leaves. Care must be taken that the leaves be not scorched in drying, and they should not be dried more than is requisite to allow of their being readily reduced to powder." These directions have been disregarded and for-

* Read before The Massachusetts Medical Society, June 6, 1910.

gotten. In 1905 I could not find that any digitalis was imported into this country in the form of powder.

Allen's English leaves have been held in high favor for many years and are largely used at the present time in Boston. They are sold in large tins, each containing a pound of leaves, including the leaf-stalk and mid-rib. The mouth of the can is a large opening, 3¼ inches in diameter, closed by a low tin cap. This original package is one that makes the proper preservation of the digitalis difficult and I know from personal observation that the cans are sometimes left open, exposing the leaves to the moisture of the air. A pound of digitalis often lasts the larger retail druggists from two to three years.

Prior to 1905 I used a number of different stocks of digitalis obtained from local pharmacists, but found none that yielded satisfactory results in the ordinary doses. I now know that this can be explained by the age of much of the leaf and by the fact that it was often insufficiently protected from the moisture of the air. I have seen digitalis offered for sale that had been in stock three years. Sometimes the leaf is already old when it reaches the city. A can of English digitalis with a potency certificate, date July, 1908, was not received by a Boston pharmacist until nearly eighteen months later. Improper drying of the digitalis may lead to rapid deterioration as Focke has shown.

I became convinced that the digitalis leaves, available in Boston, were of poor quality, so in 1905, Frank O. Guild, the pharmacist, at my request, imported from Germany some of Merck's powdered digitalis. This new powdered leaf exerted promptly the characteristic action, — slowing of the pulse and diuresis. I have repeatedly seen it act beneficially when other digitalis had failed.

The value of the German leaf was srtikingly shown in the first case in which I used it.

The patient was a middle-aged woman with chronic myocarditis. She had been under my observation since July, 1904, and was frequently seen by my colleagues at the Massachusetts General Hospital. Anasarca, dyspnea, recurring cough and scanty micturition were the chief symptoms. I had given her digitalis obtained from various local sources with no definite results. The following extract from my case-report shows strikingly the failure of the old digitalis to produce diuresis. Note made April 4, 1905: "Four days ago she was unable to void any urine. She states that for two weeks the quantity of urine has been scanty. Five days ago she consulted Dr. X., who gave the tincture of digitalis in 10-drop doses thrice daily. Yesterday he increased the amount to 12 drops. For the past three days the daily amount of urine voided has not exceeded half a pint." On the morning of April 6 she began to take 5 gr. of theocin three times a day. During the following twenty-four hours she passed nearly 4 liters of urine.

Symptoms recurred from time to time. Digitalis failed to lower the pulse-rate, or, in fact, to show any action. Early in June she was troubled with cough and dyspnea. Numerous medium-sized moist râles were heard over the lungs, and she raised considerable viscid frothy sputum. Her pulse was usually about 120 to the minute, weak, irregular and at times imperceptible. On July 24 the pulse-rate was 124 and so feeble that it could not be counted at the wrist. Note made September 20: "She has had severe cough for a week. Unable to sleep well for a month owing to nervousness; considerable dyspnea. She passes the normal amount of urine. Cough the chief symptom. *Status præsens.* Slight cyanosis of the lips; respiration a trifle labored and quickened, 32 to the minute. Cardiac impulse cannot be seen or felt. Only slight enlargement of the heart; no dullness to right of sternum; absolute cardiac dullness does not extend to the left beyond the parasternal line. Systolic bruit replaces the first sound at the apex. Both sounds heard at the base. Cardiac action irregular. Pulse at the wrist so weak that it cannot be counted. Many fine, moist râles heard over both lungs, especially at the bases behind. The patient raised during the night 150 ccm. of frothy serous sputum."

The first of December, 1905, she was given the powdered digitalis from Merck, which had just been received from Germany. On Dec. 8, 1905, I noted that "the new digitalis has helped her greatly. The cough is much less, the pulse is slow but irregular and varies from 16 to 20 to the quarter. The rate at the cardiac apex is the same as at the wrist. To-day is the first time in six months that I have found the pulse below 120. The cardiac dullness is greater than it has been. She has taken about 2.5 gm. of the digitalis which I discontinued to-day." When I saw her Jan. 25, 1906, she had been taking the powdered digitalis for five days. Her pulse was slow, 76 to the minute, and of good quality. During the following five months she was in excellent condition. She did not come under observation again until July, 1906, when I noted that the patient was looking well, and much younger than I had ever seen her. The pulse was not accelerated, but was somewhat irregular in rhythm, and she was beginning to suffer again from dyspnea and cough. Although she has had since then frequent attacks of cardiac insufficiency, she has always been benefited by the German powdered leaf and is still able to do light housework. (June, 1910.)

The strength of Merck's powdered leaf and the weakness of the tincture, employed in the usual dose, was shown in the following cases:

On Dec. 10, 1909, I saw in consultation, Mr. M., aged sixty-two, who was suffering from cardiac insufficiency, the result of coronary sclerosis. When first seen by his physician on Oct. 21, 1909, his pulse was rapid and irregular. There was swelling of the feet and edema of the lungs. Shortness of breath was the chief complaint. Rest was followed by marked improvement and at the time of my first examination there was no edema and he could walk without dyspnea. Although he had taken 15 drops of a tincture of digitalis three times a day for six weeks the pulse remained rapid. In my note I stated that the

rate over the precordium was about 130 and of very irregular rhythm. Some of the beats failed to reach the wrist. The radial pulse was small; the blood tension, 195. A tracing showed the arrhythmia to be of the absolutely irregualr type. The heart was dilated to the left. No murmurs were heard. After the digitalis was discontinued for about ten days, the patient was given a prescription for 2 gm. of Merck's powdered leaf divided into pills, each containing 0.1 gm. Without consulting his doctor, he had this refilled. After he had taken three of four of the additional doses, purging, nausea and vomiting developed but disappeared promptly when the digitalis was stopped. The pulse did not become rapid again as long as he remained under observation (one month). In this case the tincture (45 drops a day) showed no definite physiological action in six weeks, while the leaf (0.3 gm. daily) produced marked toxic symptoms in eight days.

A patient in my clinic at the Massachusetts General Hospital who suffered with chronic passive congestion of the lungs attended by cough and spitting of blood obtained no relief from a digitalis tincture in the ordinary dose. A few days after the administration of the active powdered leaf the cough and bloody expectoration ceased.

Some physicians have told me that they never see any benefit result from the digitalis they prescribe, and I know of instances in which the tincture has been given in large doses for a long time without toxic manifestations supervening. Dr. George C. Smith has related to me the case of a patient seen by him in consultation who had taken 30 drops of a digitalis tincture three times a day for six weeks without any apparent result.

Attention should be called to the fact that the tincture is generally given in too small doses to produce a prompt physiological effect. A tenth of a gram of digitalis is the usual dose of the powder. This corresponds to 1 ccm. (15 minims) of the tincture, but a cubic centimeter will be found to contain 35 to 40 drops of the tincture when the ordinary medicine dropper is used. Hirschfelder, [15] in his recent work on diseases of the heart, recommends large initial doses of digitalis. If Withering's directions for the administration of digitalis were followed, the use of an inert drug would readily be detected. "Let the medicine," he said, "be continued until it either acts on the kidneys, the stomach, the pulse or the bowels; let it be stopped upon the first appearance of any one of these effects."

Fraenkel [16] showed that six infusions obtained in Heidelberg and vicinity varied in toxic dose from 100 to 275%; six tinctures from 100 to 400%. Edmunds [17] in Ann Arbor, examined seventeen tinctures of digitalis and found great variation in strength. Two "standardized" preparations from one manufacturer were examined, and one was found to be twice as toxic as the other. Edmunds and Hale, in their admirable monograph, present a complete résumé of the literature dealing with the standardization of digitalis.

BIOLOGICAL TESTS OF DIGITALIS.

It is generally admitted that the value of digitalis preparations can be more accurately determined by biological rather than by chemical tests. The amount of digitalis required to stop the heart of a frog in systole is the most accurate indicator of its strength, and is the basic principle of various frog-heart methods.

Twelve-hour method. — This was introduced by Houghton,[4] 1898, for the physiological assay of strophanthus.

Twenty-four-hour method. — Buehrer [18] ascertained the smallest amount of the drug that produced systolic stand-still of the heart within twenty-four hours.

One-hour method. — This was first employed by Albert Fraenkel [16] working in Gottlieb's laboratory, in 1902. It is recommended by Edmunds and Hale,[8] who conclude from their study that it is superior to the perfusion method or to that of Focke.

Perfusion method. — Using William's apparatus, Santesson [19] determined the lethal dose by adding digitalis to the fluid used in perfusing the isolated heart. Edmunds and Hale [11] measured the time required to stop the isolated heart with digitalis contained in Ringer's solution.

Focke's method. — Focke [20] ascertained the amount of a 10% infusion that would cause the heart to stop in systole in a frog of about 30 gm. weight (*Rana temporaria*) within the time limit of seven to twenty-five minutes. The operating room was kept as nearly as possible at a constant temperature, whether the tests were made in summer or winter. Focke expresses the potency of the drug by the following formula: $V=\frac{p}{d\times t}$. The toxic value (V) is determined by dividing the weight of the frog (p) by the quantity (d) of the drug, — 10% infusion — multiplied by the time for systolic standstill of the heart to occur. For example $V=\frac{30}{0.6\times 10}=5$. According to Focke, good digitalis leaves give a value of 5 ($V=5$).

Thirty-minute method. — Gottlieb [21] and Fraenkel [22] now recommend the thirty-minute method, although in his early work Fraenkel used the time limit of one hour. They determined the amount of digitalis necessary to produce systolic standstill of the heart in exactly thirty minutes. They introduced the "frog unit" which is analagous to the antitoxin unit. Their frog unit is the amount of digitalis required to stop the heart in systole of a frog weighing 30 gm. in thirty minutes. Fraenkel states that a gm. of good digitalis should contain 50 frog units.

EXPERIMENTAL STUDY.

The thirty-minute method was used and an effort made to select frogs weighing 30 gm., but owing to the limited supply it was necessary to use lighter and heavier ones as well. The frogs were weighed to within the limits of one gm., and the dose of digitalis per gm. of body weight was calculated. With the aid of Professor Cannon, the experiments were made in the physiological

laboratory of the Harvard Medical School during the months of December and January. The frogs were brought to the operating room from the cold tank a few hours previous to the tests, and kept in a glass receptacle containing a little water. The temperature of the room was usually 20° C., and never varied more than 1°. A freshly prepared 10% digitalis infusion was injected into the ventral lymph sac. The frogs were then placed under bell jars containing pads of well-moistened filter paper. At the end of thirty minutes the animals were pithed, fastened to frog boards and the heart exposed in the usual manner. When the drug had exerted its characteristic toxic action the ventricle was found pale, contracted and motionless. If the heart was beating, larger amounts of the drug were given to other frogs; if in systolic standstill, smaller doses. My experiments were carried out on *Rana pipiens* as were those of Edmunds and Hale. The European observers have found *Rana temporaria* more susceptible to digitalis poisoning than *Rana esculenta*. I have reason to believe that the American frog (*Rana pipiens*) requires a considerably larger dose of digitalis to produce systolic standstill than *Rana temporaria*. A study of the tables published by Edmunds and Hale show that none of the digitalis preparations they examined by Focke's method had a value (*V*) of more than 3.8, although Focke has stated that a good leaf should yield the value of 5.

During the past winter I tested digitalis leaves obtained fron six of the leading apothecaries in Boston, and from one in a suburban town, and from the pharmacies of the two largest hospitals. I also examined some powdered digitalis recently imported by Parke, Davis & Co., and kindly furnished to me by that firm's department of experimental medicine. I used as a control in my work powdered leaf prepared by Cæsar and Loretz, of Halle, and the tests were made a short time after it was received from Germany.* The leaf had been standardized physiologically in Germany by Cæsar and Loretz, and its strength measured by Focke's method was "*V* = 5 or O. 4 *gm.* = 100 *gm.*" frog weight. This titrated leaf comes in small mouthed bottles containing only 50 gm. A conspicuous label cautions the dispenser to keep the powder in a dry place.

The powdered digitalis of Cæsar and Loretz was found to be the most active of any tested; 1.4 mgm. per gram of frog weight was found sufficient to produce systolic arrest of the heart in thirty minutes. As small a dose as 0.8 mgm. caused the death of a frog within one hour, as is shown in the accompanying table.

TABLE I.

THE DETERMINATION OF THE AMOUNT OF DIGITALIS REQUIRED TO PRODUCE SYSTOLIC STANDSTILL OF THE HEART OF RANA PIPIENS IN THIRTY MINUTES.

Protocol Number.	Amount of digitalis per gram of frog weight.	Results.
4	.0004	− 1 hr.
6	.0008	− + 1 hr.
10	.0008	− + 1 hr.
54	.0010	− + 1 hr.
68	.0010	− + 1 hr.
55	.0012	−
69	.0012	−
58	.0013	− (digitalis not well absorbed)
29	.0014	+
34	.0015	+
8	.0026	+

* This was obtained through the kindness of Dr. Leo Mueller, of the Heidelberg Medical Clinic.

By far the best preparation I found on sale in Boston was the leaf put up by Merck; 2 mgm. of this preparation was the lethal dose per gm. of frog weight, but 1.5 mgm. per gm. of frog weight was not sufficient to kill the animal. The powdered leaf recently imported by Parke, Davis & Co., killed a frog when 3.5 mgm. per gm. of frog weight were given.

TABLE II.

MINIMUM DOSE OF DIGITALIS LEAF PER GRAM OF FROG WEIGHT REQUIRED TO PRODUCE SYSTOLIC STANDSTILL OF THE HEART OF RANA PIPIENS IN THIRTY MINUTES.

Cæsar and Loretz: Powdered digitalis leaf,	.0014 gm.
Merck: Powdered digitalis leaf,	.0020
Parke, Davis & Co.: Powdered digitalis leaf,	.0035
Allen: Digitalis leaf, Hospital Y,	.0040
Squibb: Digitalis leaf, Apothecary D,	.0040

Five different lots of Allen's English leaf obtained from four druggists in Boston and from Hospital Y were tested. Not one of these samples exerted any digitalis action when 3 mgm. were given. The preparation obtained from the hospital gave a positive result when 4 mgm. were used. Two specimens of Allen's preparations digitalis were tested in still stronger solutions, and 5 mgm. per gm. of frog weight were not sufficient to stop a frog's heart. Without doubt the preparations were once active, but had lost their strength through age and exposure to the air. Deterioration may occur before a can is opened as the following shows: On Jan. 20, 1910, I examined a supply of digitalis that had just been received by a local druggist. On the outside of the tin was the printed statement that on July 23, 1908, this leaf had been tested at the pharmacological laboratory in Cambridge, England, and it was found that the lethal dose was .9 mgm. for each gm. of frog weight. I found that 3 mgm. per gm. of frog weight was not sufficient to produce systolic standstill in thirty minutes. The fact that more than three times the lethal dose as determined in England failed to kill the frog in my test can scarcely be explained by the difference in species. The can contained a pound of digitalis. As the leaves had already lost much of their activity when freshly opened, it would not be surprising if they become wholly inert before the last of the pound is sold.

TABLE III.

SAMPLES OF DIGITALIS THAT FAILED TO PRODUCE SYSTOLIC STANDSTILL OF THE HEART OF RANA PIPIENS WHEN GIVEN IN THE FOLLOWING DOSES PER GRAM OF FROG WEIGHT.

Allen: Apothecary A,	.0050 gm.
Apothecary B,	.0050
Squibb: Apothecary C,	.0050
Shakers of Ayer: Apothecary E,	.0050

Two preparations of Squibb's digitalis were tested. One did not have a lethal action when 4 mgm. per gm. of frog weight were used, and the other was inactive in amounts less than 4 mgm.

A sample of digitalis prepared by the Shakers of Ayer was examined, and did not produce systolic standstill when 5 mgm. were given. This was the only digitalis leaf carried in stock by a large drug shop.

THE THERAPEUTIC USE OF ASCITIC FLUID A PRELIMINARY COMMUNICATION.*

BY TIMOTHY LEARY, M.D.,
AND
ROBERT W. HASTINGS, M.D., BOSTON.

(From the Laboratories of Pathology and Bacteriology of Tufts College Medical School and the Wards of St. Mary's Infant Hospital.)

One of the writers has felt for a long time that ascitic fluid derived from cases of mechanical obstruction of the abdominal venous circulation (e. g. alcoholic cirrhosis of the liver — broken cardiac compensation) was a valuable human saline whose use from a therapeutic standpoint would furnish more effective stimulation than could be obtained from an artificial salt solution or from a similar solution produced by diluting sea-water.

The most important objection to its use lay in the belief that ascitic fluid from such source contained toxic agents derived, in the case of cirrhosis fluid, possibly from the toxic bodies responsible for the disease, or, in the cardiac cases, from the end products of destructive metabolism of tissues.

The most complete refutation of the claims that toxic agents were present in such fluids came from Hodenpyl's intravenous use of such fluid in cancer. Hodenpyl [1] has introduced into human beings as much as two quarts of this fluid intravenously at one time without evidence of toxic effects.

Gruner,[2] under the heading "poisonous effects of exudates and transudates when injected into the blood," says: "In cirrhosis of the liver the transudate is no more poisonous than the effusion of pleurisy, showing that the portal blood is not more toxic than the blood of the general circulation."

In February of this year, we, as the result of subcutaneous and intravenous injections of ascitic fluid in enormous quantities into guinea pigs and rabbits, without evidence of toxic action, had about concluded to determine its influence on diseased conditions in children when Hodenpyl's application of cancer ascitic fluid in cancer was published. It was evident that in laboratory animals not only would toxic activity such as might be exhibited in human beings appear, but also the added effects of a serum foreign to the animals in which it was used. No toxic action was discoverable in any of our experimental animals.

CONDITIONS UNDER WHICH THE FLUID WAS USED.

St. Mary's Infant Hospital receives, from its own maternity clinic, children, many of whom are illegitimate and a percentage of whom are premature, together with many children who are sent in from other sources after treatment has proved futile. These children often exhibit in the most marked degree the characteristic picture of infantile atrophy, with the typical senile fascies, withered limbs and shrivelled body. The types of cases which appear include very largely the forms of malignant marasmus (infantile atrophy), in which the clinician often refers to syphilis and tuberculosis as the important factors in the process, although post-mortem examinations reveal no evidence of either disease.

There have been many hypotheses advanced to account for the extreme asthenia which is so common, notably in institutions, among bottle-fed children.

The literature on this subject has been reviewed by Wentworth [3] and Denny [4] and leads to the conclusion that marasmic infants who are bottle-fed do not receive certain human ferments which are essential for the proper assimilation of food. It is recognized that atrophic infants, in addition to the nutritional disturbances which they show, are lacking in resistance to infection and are carried off in large numbers by terminal infections. It is a question whether the condition which we know as infantile atrophy is not always associated with low-grade infection or sub-infection of intestinal origin (*vide* Denny, *loc. cit.*, p. 1908). Pfaundler and More [5] have demonstrated that the complement content of the blood of bottle-fed and particularly of atrophic infants is low as compared with that of breast-fed infants.

* This paper is presented as a preliminary communication for the purpose of calling attention to the apparent therapeutic value of a substance hitherto discarded as valueless or toxic. The clinical results herein described are at least suggestive. It is our intention to carry out a wide series of observations on the value of ascitic fluid in nutritional disturbances, shock and infection.

Wassermann [6] believes that the low resistance to infection shown by bottle-fed infants is exhibited because the antibodies which are produced are used up in transforming the cow albumin of the food into the human albumin of the infant, in order that it may be assimilated. The human albumin of breast milk can pass unchanged from the intestine into the circulation, requiring no intervention of ferments, which are left free to act upon invading bacteria.

Denny [4] was able to demonstrate that partial feeding with breast milk was followed by prompt improvement in two cases of atrophy and one of serious intestinal infection. He reaches the conclusion that too small amounts of human milk were used to furnish a food value which would account for the improvement. Ferments or proferments, which the infants needed and made use of, must, therefore, have been present in the human milk.

Breast feeding will, then, remove the difficulties in a large percentage of the cases. Wet nurses, however, are difficult to obtain in number sufficient to care for the large number of marasmic children who are found in a great clinic like that at St. Mary's Infant Hospital. It was, therefore, necessary to turn to other means of coaxing the nutritional apparatus of these children to do normal work.

Physiological salt solution has been strongly advocated for its stimulant action in this condition. Pfaundler has shown that its use is sometimes accompanied by increase in the complement of the blood. Since Simon [7] reported the remarkable success he had obtained with isotonic seawater in marasmic infants, we have been able to test its value on a large scale in comparison with artificial physiological saline.

It was claimed for isotonic sea-water that it contained the same salts as the blood. Simon refers to "*la presque identité de composition minérale du plasma sanguin*" which sea-water shows. The salts are in such relation that dilution to produce isotonicity is not accompanied by precipitation. This is in marked contrast to the precipitation which appears when an effort is made to produce an artificial saline by adding to water the blood salts in the quantities in which they occur in serum. The salts of blood serum exist in organic combination with the proteids of the serum, and disturbance of this organic combination gives rise to precipitation.

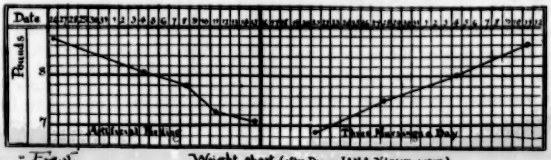

Fig 5.

The results from the subcutaneous injection of isotonic sea-water in our series [8] did not correspond to those obtained by Simon. They did not indicate that isotonic sea-water had a sufficiently greater value than physiological salt solution to justify the expense and the time consumed in obtaining and preparing it. Neither agent was satisfactory in advanced cases.

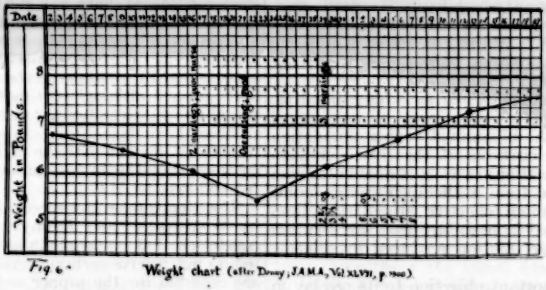

Fig 6.

CHARACTER OF ASCITIC FLUID.

Ascitic fluid is a human saline whose salts are those of the blood serum. It is usually isotonic with blood serum, the variations in freezing-point being no greater than blood serum may show. The salts are in organic combination with human proteids, which are readily absorbed.

In addition to the stimulant and food value of the fluid, it has other properties which make it desirable. It is richer in complement than is breast milk.

[7] Applications thérapeutiques de l'eau de mer. Paris, Masson, 1908.
[8] Merrick: Arch. Pediat., July, 1910.

An observation extending over a long period has shown that it is practically impossible to cultivate pathogenic bacteria in the undiluted ascitic fluid. When diluted it makes a good culture medium for these organisms, but this is equally true of blood serum. Contamination with spore bearing, dust organisms (non pathogens) is followed by growth.

Opalescent (chyliform) fluids are particularly resistant to contamination. Their keeping qualities have been referred to by many writers. They are rich in globulins, the substances which in blood serum contain the antibodies. The natural freedom from infection of ascitic fluid in the abdomen is apparently due to these antibodies.

Ascitic fluid is a transudate produced as a result of local passive hyperemia. The Bier method of treating infections depends upon flushing the infected area with a transudate resulting from the passive hyperemia which is artificially produced. The antibodies in this transudate are of assistance in destroying bacteria in the local focus of infection.

THE PRACTICAL HANDLING OF ASCITIC FLUID.

The following methods of handling ascitic fluid have been tested now in over two years' work with such fluids and have made it possible to eliminate almost wholly contamination by dust or other organisms.

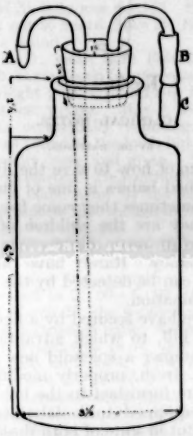

Fig. 1.

The fluid is received in a standard liter bottle (Figs. 1 and 2) supplied with a rubber stopper through which pass two glass tubes, which are bent down over edge of stopper. The tube (*A*) through which the fluid flows into the flask, runs to the bottom of flask. Its exposed end is guarded by a rubber tip. The other tube extends only to the bottom of the stopper and bears on its exposed end a cotton air filter. This consists of a piece of glass tubing filled tightly with cotton and attached to the exposed end of glass tube by a short piece of heavy rubber tubing (*B*). When receiving fluid, the rubber tip is removed from tube (*A*), to which is then fitted the rubber tubing connected with the trocar in the abdominal wall. The bottle fills by gravity. When filled, the rubber tubing is transferred to the glass receiving tube of another bottle and the rubber tip replaced, thus sealing bacteriologically the bottle. For transportation it is desirable that a pinchcock be placed on the rubber tubing (*B*) connecting the air filter with the glass tubing.

With this form of container it is possible to manipulate ascitic fluid with little danger or contamination. A tube connected with the foot pump is attached to the air filter, a delivery tube (*D*) consisting of a piece of rubber tubing and supplied with a pinchcock replaces the rubber tip on exposed end of receiving tube, and air pressure (the air passing through cotton filter) drives the fluid from the bottle into test tubes or other containers.

For injection purposes syringes which have a large capacity are expensive or unsatisfactory. We have, therefore, made use of a container adapted from the description of the container used by Dr. Robert Simon for isotonic sea-water. This consists of a glass tube of large caliber (Figs. 3 and 4) with ends drawn out, one end being bent back parallel to the main tube. To fill this, a second piece of glass tubing (*H*) is fitted by means of a rubber connection (*J*) to the end which is turned back. This piece of glass tubing is of sufficient length to parallel the main tube to its other end. The end of this tube is guarded with a

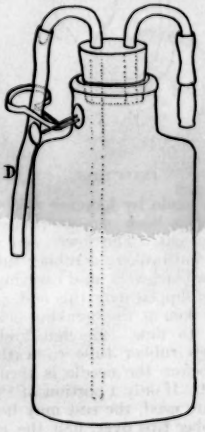

Fig. 2.

rubber tip. The end of the main tube is filled with cotton and the whole apparatus is sterilized in the autoclave.

Filling is accomplished by removing rubber tip and connecting by rubber delivery tube (*D*) guarded with a pinchcock, which is attached to the

bottle of ascitic fluid. By means of air pressure (foot pump) the container is filled to a proper level. The cotton in end (*M*) is flamed and removed and the end of tube sealed, being drawn out at one point for breaking. The rubber connection of other end is separated and this end sealed in like fashion.

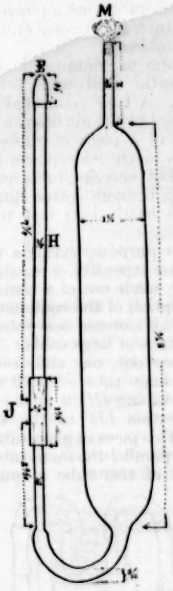

Fig. 3.

INJECTION.

Injection is made by hanging this tube by its curved end over a hook or other projection above the bed of patient. The lower end (*P*) having been flamed, and broken, a rubber tube of small caliber, with a pinchcock, and carrying the injecting needle, is slipped over this end. The upper tube (*O*) is broken at the breaking point and the fluid allowed to flow. Enough fluid should be passed through rubber tube to wash away all rubber dust before the needle is thrust through skin of patient. If only a portion of the contents of container are used, the rest may be conserved by fitting rubber tips over, first the curved end, and then, after the removal of the injection tube, over the straight lower end.

A large hypodermic needle is thrust into the subcutaneous fat or muscle. Injections have been made largely in the gluteal region, the back or the abdominal wall. One ounce of fluid has been introduced daily when the supply was obtainable. (This is probably too small a dose to use where the emergency is serious or where prompt results are desired. We are now using larger doses.)

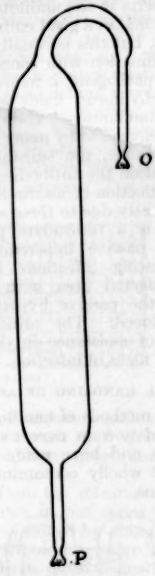

Fig. 4.

CLINICAL NOTES.

BY DR. HASTINGS.

The problem of how to save the lives of feeble, poorly nourished babies is one of our most difficult ones. Sometimes they come from the courts. More often they are the children of young girls who have lived in terror of detection during most of their pregnancy. Rarely have they any gross lesions which can be detected by the most careful physical examination.

Fresh air we have secured by a fine location on the top of a hill, to which advantage has been added this summer a splendid new suite of sun rooms. Pure, fresh, properly modified and prepared foods are furnished to the babies from one of the best-equipped milk laboratories in any institution. But in spite of both these advantages the diagnosis "marasmus" must often be put on a death certificate, and nothing more definite is possible.

New modifications of foods, preparations of digestants, digestive, nervous or general tonics or stimulants, and subcutaneous treatments, we have tried one after the other. Often a short series of cases have gained, but soon others precisely similar in appearance have failed to receive any benefit.

None of these agents has so continuously helped as ascitic fluid, so far as my records go. Though interrupted at times by failure to secure an ade-

quate supply, its administration has been followed by results which have amazed us.

Again and again, on successive visits, have I found babies whom I fully expected to find dead, not only holding their own, but making a small gain.

The cases are few in number and the report is only suggestive. There have been no failures of absorption, no local or general disturbance. These notes are brief, intended to cover only points of nutrition.

Case I. J. F., male, born Dec. 14, 1909. Admitted March 12, 1910. Weight 11 lb. 3 oz. Started on 1 : 50 – 6 : 00 – 0 : 50, increasing strength of food gradually to 2 : 00 – 6 : 00 – 1 : 00 on March 29. Curds appeared March 23, but disappeared after the addition of CaCl. gr. one t.i.d. Continued till April 15, but he lost in weight, reaching 8 lb. 15 oz. on April 13.

On 3½ oz. ten times a day of 2 : 00 – 6 : 00 – 1 : 50 he gained an ounce or two, but May 6 he weighed only 8 lb., 9 oz. Ascitic fluid was given ℥i daily from May 6. May 10 a bloody discharge from his nose was found to contain K.L. He was isolated. May 20, he developed bronchopneumonia and died May 27.

Case II. J. McB., male, born Feb. 28, 1910. Admitted April 1. Weight 7 lb. 14 oz.

Started on 1 : 50 – 6 : 00 – 0 : 50. Had an abscess of left breast. Food was gradually made stronger, but lost weight. Dejections became loose and green and April 28 dextrinised barley water was added to his food. Dejections became normal, but he continued to lose weight. May 16, his weight was 6 lb. 11 oz., and ascitic acid fluid ℥i daily was started. He gained 5 oz. and then went out to board May 25, 1910. June 15, he had gained a pound.

Case III. L. D., male, born Feb. 23, 1910. Admitted April 10, having been fed on equal parts of milk and water. Weight 9 lb. 2 oz. Took 1 : 50 – 6 : 00 – 1 : 00 well, but lost weight. May 2, weight was 8 lb. 2 oz. and was occasionally vomiting. Dextrinised barley water was added to the food, but the dejections continued generally loose and green. May 5, ascitic fluid ℥i daily was started. He continued to lose weight and May 23 was taken home by the mother weighing 6 lb. 14 oz. She reports that though feeble he is gaining a little in weight and strength.

Case IV. M. F., female, born Feb. 3, 1910. Admitted March 3, 1910. Weight 6 lb. 14 oz. Digestion was fairly good and the strength of her food was gradually increased to 2 : 00 – 6 : 00 – 1 : 00, but she lost weight till March 23, she weighed only 5 lb. 1 oz. The addition of dextrinised barley water had but little effect. May 24, weight 4 lb. 14 oz. She was started on ascitic fluid ℥i daily on June 4. June 10, weight 5 lb. She was taking well 15 oz. of 2 : 00 – 6 : 00 – 1 : 50 with 10 oz. of dextrinised barley water.

Case V. M. D., female, born April 15, 1910. Admitted April 21. Weight 6 lb. 12 oz.

At first she had poor digestion and sore eyes, and her weight dropped to 5 lb. 4 oz. on May 16. She took 20 oz. of 1 : 75 – 6 : 00 – 1 : 00, but became very weak, requiring brandy and strychnia. May 31, ascitic fluid ℥i daily was started. She has gained in strength, takes and digests 25 oz. of 2 : 00 – 6 : 00 – 1 : 00, though her weight June 10 was 5 lb.

Case VI. V. C., male, born March 13, 1910. Admitted March 25. Weight 6 lb. 3 oz. Took 1 : 50 – 6 : 00 – 0 : 50 and then 1 : 50 – 6 : 00 – 1 : 00, but lost weight. April 15, weight 5 lb. 13 oz. digesting well 15 oz. of 1 : 50 – 6 : 00 – 1 : 00, was started on ascitic fluid ℥i daily. Weight dropped to 5 lb. 4 oz. and then to 5 lb. 2 oz. The strength of the food was increased to 2 : 00 – 6 : 00 – 1 : 00 and dextrinised barley water added. From May 6 to 13 brandy and strychnia were

Fig. 9.

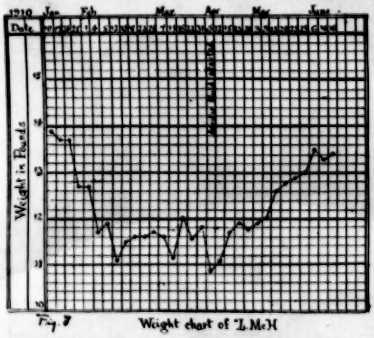
needed. June 10, has gained a little to 5 lb. 6 oz. and is taking well 25 oz. of 2 : 00 – 6 : 00 – 1 : 50 and 5 oz. of dextrinised barley water daily.

Fig. 10.

Case VII. H. H., male, born Nov. 18, 1909. Admitted March 7, 1910. Weight 11 lb. Started on 1 : 50 – 6 : 00 – 1 : 00, which he took well. Had eczema. Digestion was variable, occasional vomiting becoming more frequent. Dextrinised barley water gave no relief. May 10, weight 8 lb. 10 oz., was started

on ascitic fluid ℥i daily. Has had general skin infection and now a parotid abscess. Is taking well 40 oz. of equal parts of 2 : 00 – 6 : 00 – 1 : 50 and dextrinised barley water, but weight June 10 is 7 lb. 8 oz.

Case VIII. E. B., female, born Jan. 6, 1910. Admitted March 21. Weight 8 lb. 4 oz.

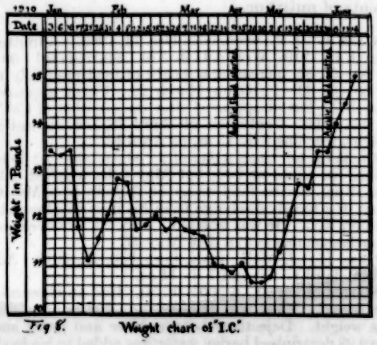


Digestion was poor, vomited all food except whey. Weight, April 19, 6 lb. 8 oz. and was started on ascitic fluid ℥i daily. Weight dropped to 5 lb. 10 oz. A little cream was added to whey and began to gain, reaching, May 20, 7 lb. 3 oz. Since then has not quite held her own. On June 20, weight was 6 lb. 13 oz., a gain of 6 oz. in ten days and was taking well 28 oz. of whey with 4 oz. of 10% cream daily.

Case IX. A. McN., female, born Feb. 25, 1910. Admitted March 15. Weight 5 lb. 15 oz. Digestion poor at first, gradually improved, till April 17 she was taking and digesting well 20 oz. of 1 : 50 – 6 : 00 – 1 : 00, but her weight was only 5 lb. 2 oz. She was given ascitic fluid ℥i daily, and has gained steadily though slowly till now she takes 35 oz. of 2 : 00 – 6 : 00 – 1 : 25 and June 10, weight was 6 lb. 2 oz.

Case X. A. G., female, born Jan. 20, 1909. Admitted April 27, 1909. Weight 10 lb. 9 oz. For a year weight fluctuated between 9 lb. and 10 lb., touching 11 lb. in September, 1909.

In December, 1909, had diphtheria, after which weight was 8 lb. 11 oz. Was started on whey, to which 10% cream was gradually added till April 8, 1910, when she was taking 35 oz. whey and 5 oz. 10% cream and weighed 9 lb. Was given ascitic fluid ℥i daily. May 16, weighed 9 lb. 12 oz. Food was changed to equal parts of whole milk and dextrinised barley water, gradually strengthened to milk 35 oz. barley water 5 oz. Weight June 10, 1910, 10 lb. 2 oz.



Case XI. L. McH., female, born April 27, 1909. Admitted Jan. 10, 1910. Weight 13 lb. 12 oz. Was given whole milk 30 oz. and barley water 10 oz. She

did well till Jan. 26, when she began to vomit. Food was diluted and digestion improved, but she lost weight till Feb. 11 it was only 11 lb. Stronger food resulted in loose dejections. April 5, she was taking well whole milk 35 oz., barley water 5 oz., but weighed 10 lb. 14 oz. Therefore ascitic fluid ℥i daily was given. Has gained steadily. Now on whole milk and cereals and weighed, June 10, 13 lb. 6 oz.

Case XII. I. C., female, born Nov. 9, 1908. Admitted Jan. 3, 1910. Weight 13 lb. 7 oz.

Started on whole milk and barley water. Lost weight till Jan. 21 she weighed 11 lb. 3 oz. She then gained to 12 lb. and remained there for two months. Had skin infections and March 17 to 26 bronchopneumonia. Became very much exhausted. April 7, weight 10 lb. 12 oz. Digesting well 35 oz. whey and 5 oz. 10% cream, was started on ascitic fluid ℥i daily. Lost a little weight, but gained strength. April 26, food was made whole milk 30 oz. and barley water 10 oz. Soon began to gain rapidly. May 13, weight 12 lb., was put on whole milk and cereals. May 31, weight 13 lb. 6 oz., ascitic fluid was omitted. Has continued to gain. June 11, weight 14 lb. 7 oz.

We desire to obtain ascitic fluid in quantity for the purpose of carrying on this work. Physicians in Boston and suburbs who are about to tap cases of alcoholic cirrhosis are requested to notify the laboratory (Telephone, Back Bay 3491 or 3492). A physician will be sent who will assist in collecting the fluid.

These photographs are reproduced merely to indicate the type of cases treated. Unfortunately, photographs were not made in the beginning of treatment of cases which have shown marked improvement.

MEDICAL SOCIAL SERVICE WORK.

BY WILLIAM R. WOODBURY, M.D.,
Head of Department for Nervous Diseases, Boston Dispensary.

A new vocation is open to women and men — medical social service work. This vocation offers to those who have the right qualifications a broad and interesting field of usefulness. It brings fair remuneration; in executive positions, a generous salary is given.

In the practice of medicine the real test is in the handling of the case. Naming the disease is but the beginning. To feel through the facts for the human story, and straightway to get down to

a practical working basis, a common point from which the patient and the physician can begin to co-operate intelligently and fully, are important factors in correcting and relieving the conditions which cause sickness and distress. The successful physician is to be the man or woman who has close acquaintance with human nature, broad sympathies, and power to make practical use of his knowledge of economic, family and social conditions. To obtain desired results with no loss of time and effort, all these factors should be set working concertedly in a carefully ordered way. To accomplish this with the large and pressing demands of a hospital service, and particularly in an out-patient service, requires the help of wise and tactful visitors who can aid in establishing in the home and its every-day family and individual life the conditions which make for health; who can help encourage the practice of that daily care which assures physical, mental and moral well-being.

The physician and his visitor should know the whole story. Sympathetic inquiry into home and living conditions is necessary; it shakes down useful facts. Too frequently people are creators of their own mental and physical misfortunes; they create, too, the misfortunes of those with whom they live. Most people need applied hygiene; and they need it most who through unwholesome or careless living are compelled to seek in hospitals and dispensaries relief from physical suffering. For those who acquire nervous diseases or conditions which result in disturbed nervous balance, this is particularly true. The presence of the medical social service visitor at the consultations of the physician and the patient establishes at the very beginning a feeling of good fellowship. The patient is assured that a sincere personal interest is being taken by the physician; that he is using his fullest power to help the patient help herself. To the visitor it gives a thorough knowledge of the physical condition of the patient; it reveals facts which the visitor should know and cannot discover easily without the physician's help. The patient and the visitor start with a mutual understanding; and follow-up work at the clinic and in the home is not confronted with suspicions or doubts. The patient feels that she has a genuine friend and helper in the visitor; and both of them know that they have in the physician a common, just and sympathetic counsellor. Straightway effective work is set going.

The visitor's work is to obtain accurate information of the manner of living, home and working conditions, and of the environment of the patient. Not infrequently facts which are of importance, which bear closely on the illness, are ignored or overlooked. She imparts to those whom she seeks to help knowledge which they can use; aids them to appreciate its practical and economic value; and shows them how to make the best application of it.

A medical social service worker should possess the qualifications of a social worker and a nurse. It is not necessary that she be a trained nurse, but she should have some knowledge of practical home-care in sickness. The ideal visitor is one who has had a social worker's and a nurse's training, with a not too great inequality on either side. First of all, she should have those womanly qualities which always make her a welcome, trusted and helpful visitor in the home. She needs close and sympathetic acquaintance with all kinds of people, and the broadest sympathies; these come from practical working experience as a social worker. She must know how to make wise application of first-hand, practical knowledge of economic and social conditions; mere impulsive sympathy generously spent is not social service. She should have the capacity to understand human nature; a frank sympathy combined with good judgment is an essential part of her equipment. With patience, tact and a habit of making haste slowly, the wise visitor helps the physician secure the willing co-operation of the woman, child or man who seeks relief. Good physical health is required of the medical social service worker, for the work is not easy. Many discouragements are sure to be met — discouragements which can be met successfully only with abundant health, generous optimism, and an abysmal sense of humor. Many of the problems which fall to the hospital visitor are difficult. Success comes only through organized effort; and the visitor must have the capacity and willingness to do good team work.

In every form of physical or mental incapacity the tactful visitor can accomplish much good. She is indispensable in helping the physician secure for those who are afflicted with chronic sickness positive and useful relief and larger comforts. She can bring to the family and to the patient many kinds of substantial assistance in adjusting themselves to conditions so that the burden of the sickness may be carried more comfortably. Knowing the organizations and institutions for providing relief and assistance to those in need, and being in close working relations with them through their executive heads, the medical social service worker secures promptly the assistance needed; and its proper use is safeguarded.

The medical social service worker is the one person who should best be able to give the right assistance to the unmarried woman who is pregnant. Work with these young women makes large demands on patience, tact and good sense. There is no form of practical philanthropy which calls for more painstaking and sympathetic consideration than the much-needed aid offered these girls. They should receive in the right way more real help than is generally given them. The price in suffering exacted from them in a natural way demands that the world's rough hand should not fall too heavily on them; the misfortune is not their fault always. During this stressful period lofty moral talk which humiliates and emphasizes a human weakness does not help. The young woman should be encouraged to meet as cheerfully as she can and in a practical self-respecting way her immediate serious condition. This the medical visitor does by dissuading the girl from

deliberately wrecking her health for all time; by offering congenial refuge and work until the time comes for going to a hospital; by helping the mother find for herself and her child a right kind of home; and by trying to bring her to the right point of view towards sex relations. The medical social service worker is a real friend to these young women — a friend whom they never forget.

Hospitals and dispensaries, realizing the necessity of following-up those who come to them for relief, are beginning to establish social service departments as essential and organized part of their equipment. No medical institution does its full work towards relief of sickness and physical incapacity when its interest in the patient ends at the hospital door. All-round help and effective relief demands at least some first-hand knowledge of the conditions which obtain for the patient in the home, and the demands and environment of the working hours. The one department of a hospital or dispensary which does the most to help the physician complete his work is the medical social service department. Its usefulness and its need are fundamental. Without such a department the efforts of an institution are crippled and imperfectly effective. This department should be a structural part of the institution, directed and managed by the governing board; and organized and equipped to give ready co-operation with all the departments of the hospital and dispensary; and to exchange co-operative effort with the executives of other institutions working to promote physical and social efficiency. The two years' experience with its medical social service department at the Boston Dispen leaves nosary doubt as to its meeting a long-felt need, and as to its practical usefulness. More thorough work is now being done at the Boston Dispensary than ever before, and the results both for the institution and those who seek its help are made more permanent.

THE METEOROLOGIC AND HYGIENIC ASPECTS OF THE FLOODS IN FRANCE IN 1910.*

BY GUY HINSDALE, M.D., HOT SPRINGS, VA.

Fellow of the Royal Society of Medicine, Secretary of the American Climatological Association.

The flood of the river Seine in January, 1910, was so extraordinary and produced such widespread distress and world-wide sympathy for the sufferers that a record of this event should be made in the Climatological Society's transactions. The writer was in Paris throughout the flood and watched the river rise for ten days before it reached its maximum. During this period there were some rainy days, and the rainfall had been considerably above the average. In 1909 the rainfall recorded at Parc Saint Maur Observatory was 26.5 in. and there was a great deal too much proportionately in the last three months of the year. The average annual rainfall for Paris is 22.50 in., or 574 mm. The average for January is 40 mm., or 1 in. For January, 1910, the rainfall amounted to 74 mm., or nearly 2 in.

The rainfall for Paris is thus about five eighths that of New York or Philadelphia. We may note, in passing that the snowfall in France was very light during January and was scarcely sufficient to insure good winter sports in the French Alps. The temperature in France was unusually mild during the past winter and well above the freezing point through January. The grass, as usual, remained green in Paris and its environs. Conditions were, then, favorable to thawing and not to freezing even in the higher portion of the Seine.

Paris is about 110 miles from the mouth of the river, which is navigable to the sea. The watershed of the Seine reaches a height of not over 700 to 800 meters (2,500 ft.) and covers about 80,000 sq. km. Some of this watershed is permeable, but about a fourth of it is only partly permeable, and hence lends itself rather easily to quick and torrential drainage. In the permeable area the water is first completely absorbed by the soil and then oozes out to collect at low-lying points and from water courses, the floods of which rise gradually and, though not very high, are of long duration.

The Seine watershed is classified under both characters, and it is shown that in times of continued rain, such as occurred in January, the torrential tributaries are the first to fill and their floods reach the main stream before those of the slower tributaries. But as the rain continues, the latter swell gradually and continuously, while meantime the torrential streams rise several times their natural size, until their floods add themselves to the waters of the slow streams now swollen to the greatest extent. Thus the geographic conditions of the Seine basin in continued rainy weather permit the coincidence of the successive floods of a certain number of tributaries, and sometimes, as has been the case this year, of most of them.

These coincidences, which depend on the simultaneous occurrence of prolonged rains throughout the basin, are evidently somewhat uncommon. Such floods as we saw in 1910 we shall probably in the nature of things never see again; at least such a flood has not been witnessed since 1658.

We have, then, a rainfall slightly in excess of the normal; a mild winter and imperfect drainage of the Seine, and the result is a stupendous flood. We confess that, on superficial view, the apparent causes seem greatly out of proportion to the tremendous results, and we cannot see why such floods may not easily be repeated.

The Seine at Paris is formed by the union of the Yonne, the Marne and the Upper Seine. The latter is a slow river; the Yonne is decidedly torrential; the Marne drains a basin which is partly permeable and partly impermeable. But in times of freshet the whole area is well saturated and the distinction between permeable and impermeable areas is very indefinite.

It has been calculated that a flood in the

* From a paper read at the twenty-seventh annual meeting of the American Climatological Association, May 4, 1910.

torrential streams reaches Paris in three or four days from the more distant parts of the basin,[1] while the corresponding flood of the lower streams is at least three or four days later.

These meteorological and geographical features must be reckoned with if Paris is to be spared another disaster.

M. Camille Flammarion, the French astronomer, has recalled what the late emperor of the French, Napoleon III, wrote in his essay on the extinction of pauperism: "The sun absorbs vapors to distribute them as rain over places which need water. When this restitution takes place regularly, fertility is the result; but if the sky in its wrath sheds partially in storms and tempest the vapors which it has absorbed, the germs of production are destroyed and sterility is the result. The distribution makes all the difference. If it is equitable and regular, it creates abundance. If it is prodigal and partial, it brings on a dearth." In fact, it is the irregular distribution of rain that brings on disaster.

Under Napoleon III, M. Belgrand, the engineer of the water and sewers department of Paris, established a hydrometric service which enables one to foretell the state of the river twenty-four to forty-eight hours in advance.

How much deforestration has influenced the recent flood is not clear. As far as I have been able to learn, the watershed of the Seine has not undergone marked alterations by deforestration in recent years. The Seine basin is shallow and there is no permanent snow; the steeper slopes are occupied by vines and pastures. There are some large areas of soil of calcareous oölite which are well suited for the growth of pine-trees. As a preventive measure afforestration affords some hope. On Jan. 31 a resolution was adopted by the Council General of the Marne Department urging the government to prevent further deforestration by imposing prohibitive taxes upon timber cutting in the nature of deforestration, and by freeing plantations of young trees from existing taxes. Replantation has been successfully accomplished in the desolate tracts of Champagne-Ponilleuse, where large groves of pine are in vigorous growth.

It will be a very interesting thing to watch the effect of this flood on the occurrence of disease. It must be understood that the waters encroached on some two thousand acres in Paris, along seven miles of the course of the Seine, and many hundreds of square miles above and below the city. Aside from the encroachment of the river, extensive areas filled with water from the sewers. There are hundreds of miles of sewers and two partly underground rivers, the Bievre and Grande Botel Betliere in Paris.[2] When the river Seine rises to an unusual level there is a back pressure into these sewers and a difficult or sluggish exit of contents; add to this the drainage from streets and houses, and it is not surprising that breaks occur, the contents flooding thousands of cellars, emerging in the streets and at their subsidence leaving a nasty, foul-smelling deposit, implanting in thousands of homes the danger of disease.

What diseases may we expect? Time only will determine. The French have instituted very active and extensive methods of disinfection and will certainly handle this matter on the best scientific lines.

We naturally first think of epidemic diseases like typhoid fever. We remember the great amount of typhoid that followed the flood at Johnstown, Pa., in May, 1889. It is a matter of record, also, that in Rome, in 589, a great pestilence followed the inundation of the Tiber.[3] Instances no doubt could be multiplied.

Bacteriologists state that the vitality of the typhoid bacillus is comparatively small in the presence of the innumerable organisms always present in sewage and sewers. This would seem to minimize the danger from sewage deposits as far as typhoid fever is concerned. It would not, however, be safe to rely on such assurances. The vigorous sanitary measures adopted by the French include wholesale disinfection of all inundated premises by state authorities as well as by private organizations. The Société de Secours aux Blessés Militaires, with its thirty-six branches and one hundred and fifty nurses, are doing everything possible to assist the stricken inhabitants to set their houses in order and begin life again under hygienic conditions.

Paris toward the end of winter is damp at the best, and the access of so much water into cellars will probably increase the amount of illness from influenza, tonsillitis, rheumatism, pneumonia, pleurisy, bronchitis and possibly other diseases. It would be expected that some diseases like neuralgia, gout and diarrhea or dysentery may originate or be aggravated by the cold and wet surroundings in which many thousand Parisians must live and work for months to come.

Since the above was written I have reports from Paris on good authority that no unusual sickness has occurred and that this is attributed to the very energetic methods adopted by the French authorities in meeting the conditions; the underground railway has been fully restored to use, although it was filled with water, and Paris seems to be enjoying its usual state of health.

[1] For a review of this subject, see the *Times*, London, Feb. 2, 1910.

[2] The sewers of Paris converge into large collecting sewers which discharge into the Seine at Clichy, below Paris.

[3] On the Castle St. Angelo, at Rome, is a large figure of an angel sheathing a sword in commemoration of the staying of the pestilence. The latter was very fatal, but its exact nature is not known.

Reports of Societies.

CONNECTICUT STATE MEDICAL SOCIETY.

ONE HUNDRED AND EIGHTEENTH ANNUAL MEETING. NEW HAVEN, MAY 25–26, 1910.

(Concluded from No. 6, p. 262.)

DISCUSSION.

DR. PHILIP D. BUNCE, Hartford: In general surgery, if the patient dies, he dies in an orthodox manner; and that is the end of him. If he has a fracture, however, and he has any final disability or deformity, the surgeon is judged to be the cause; and a monument

of his skill exists as long as the patient lives. In general, accurate replacement of bones gives the best results, regardless of particular kinds of splints. Severe laceration of the soft parts often makes the application of splints and supports very difficult. Sutures of soft parts should practically never be used in compound fractures. In my opinion, any method of fixation in which nails or drills are allowed to remain projecting through the skin is bad. I believe that x-ray pictures should usually not be shown to the patient.

Dr. William H. Carmalt, New Haven: I am rather surprised at the pessimism of Dr. Hawley compared with the optimism that I feel with regard to our success in the treatment of fractures. The principles of the care of fractures have not changed; we have simply got to restore the parts as nearly as we can. In these days of antiseptic surgery, there is no reason to hesitate to attack a bone that is not in good position and that you think will have a bad functional result. It is not worth while to cut down on every bone that the x-ray shows is not in perfect apposition; if, from experience, you feel that the limb is going to be useful, let well enough alone.

Dr. Samuel M. Garlick, Bridgeport: It is all very well to take the public into our confidence, provided that everything is all right, but sometimes you discover that some things are not so right as you would like to have them. Professional confidence is wise and safe, but public confidence must be very carefully scrutinized.

Dr. Hawley: We certainly see that there are a large number of deformities following fractures, and it has been impressed upon me that a large proportion of them are unnecessary. In some fractures, too much treatment is done. I think that in a good many cases, little or no treatment other than protection is necessary.

SOME PRINCIPLES OF INTRACRANIAL SURGERY.

Dr. William H. Verdi, New Haven: The greatest difficulty encountered is not in the surgical technic, but in the cerebral localization. One should not wait too long after making a diagnosis of increased pressure before decompressive measures are instituted; otherwise there is danger of a loss of vision. I do not consider operations upon the brain and cord any more dangerous than operations elsewhere. The most troublesome thing encountered is hemorrhage; and infection is the second chief factor in the mortality of these operations. In my whole series of cases, however, I was obliged to stop only once on account of hemorrhage; and the only case of infection was that of a child operated on for a tumor of the cerebellum that at the time of operation proved to be a tuberculoma. This operation was performed in a private house, and the patient afterward became infected. There is nothing to be gained by the introduction of needles into the various parts of the brain in the exploration of tumors, as they usually have a consistency not very different from the brain itself. An operation for decompression is indicated in all cases that cannot be localized. I have seen the administration of iodides and mercury to patients with symptoms of intracranial pressure kept up until the patient's vision was destroyed. The use of chloroform or ether as the anesthetic is a mere matter of individual choice. While the results of operations for tumor of the brain are not so satsifactory as they should be, I consider the operation itself comparatively devoid of danger.

DISCUSSION.

Dr. Leonard W. Bacon, New Haven: What little I have to offer in the way of remarks is based upon a case of brain tumor in which the author of the paper was kind enough to assist me. The interesting part of the condition was the after-progress of the case. A hole was left in the brain substance as large as a turkey-egg. When we came to withdraw the last piece of gauze, and there was nothing left in the cavity to act as a cushion, we had a repetition of the pressure symptoms. For an interval of three or four days the progress of the case was somewhat in doubt. After that, the woman went along very nicely to recovery, and she is well to-day. So far as I know, this was the first case of brain tumor removed in this city with the survival of the patient. Another case was one of the largest brain abscesses that I have ever seen. There was almost complete blindness when the operation was done, and there was entire recovery except for the sight. If the operation had been done a week earlier, I think that the girl would not have been blind to-day. This emphasizes the fact brought out by the author, that when cerebral compression exists, interference must not be too long delayed.

Dr. Max Mailhouse, New Haven: I suggested to Dr. Verdi that in a case of cerebellar tumor in which there was marked bulging of the cerebellum from the great intracranial pressure, a slight incision be made between some of the laminæ, thus possibly permitting the pressure to extrude the growth. This actually took place, and the patient was saved the loss of any material amount of brain substance. This same procedure might equally well be pursued in other areas of the brain. Opinions as to the presence of neoplasms based solely upon the appearance of choked disk and pain are sometimes erroneous, as specific disease at the base may give this picture; yet when in doubt, and the optic disks are in such a condition as to threaten vision, the safest procedure for the patient is at least a decompression. In cases of fracture without extreme evidence of local injury, when the symptoms indicate increasing hemorrhage, the unilateral dilatation of the pupil is often an aid in localization. Of greater value, however, is the occurrence of unilateral convulsions on the contralateral side. That convulsive phenomena indicate cortical irritation was evidenced by the case reported by Dr. Verdi, in which, also, immediate incision of the dura at the time of the operation, in order to relieve pressure, was indicated. In the prognosis of the results after operation, one should be guarded.

Dr. William H. Carmalt, New Haven: The last sentence of Dr. Mailhouse's remarks, which was all that I heard, leads me to speak of a case of operative infiltrating glioma of the cerebellum in a patient previously operated upon unsuccessfully for decompression, the boundaries of the tumor not being made out. There has been no recurrence of the tumor since, and I think that these cases are worth putting on record.

THE TREATMENT OF TUBERCULOUS PATIENTS OUTSIDE THE SANATORIUM.

Dr. Dudley B. Deming, Waterbury: Tuberculosis is a disease that needs careful medical attention and nursing. The attempt to treat outside of sanatoria patients in the social station in which the disease abounds is a poor substitute for sanatorium treatment. The disease, however, will not be eradicated by the establishment of sanatoria that admit only incipient cases, while rejecting the advanced cases and discharging cases that they fail to improve. The latter will become advanced cases, and thus spread the disease among others. Tuberculosis may be prevented, but not without the expenditure of vast sums of money to care for advanced and chronic cases in sanatoria,

and to aid the different families thus deprived of their wage-earners. The giving of employment to uncured patients discharged from sanatoria is not unattended with danger to the community. The first and most important factor in the treatment of tuberculosis is to prevent its communication to others, and the second is to benefit the patient. Both these factors are, with the vast majority of patients, more advantageously carried out in a sanatorium than at home.

DISCUSSION.

Dr. David R. Lyman, Wallingford: There is no case of tuberculosis that does not have to be treated outside the sanatorium. Practically all that the sanatorium does is to arrest the disease. Every tuberculosis patient needs treatment for years after he gets home. The most dangerous point in the case is when the patient has got where he looks and feels perfectly well. He then has an anatomical tuberculosis, but not a clinical one; but he must be watched for several years in order to make certain that the anatomical disease does not become clinical. We often see cases of tuberculosis carried on to arrest by the general practitioner as thoroughly as in any sanatorium, but this is not enough. He should be instructed to come back for examination at regular intervals, whether he is feeling badly or not. I do not believe that a good, light, indoor occupation is as bad for such persons as it is considered to be. If you can regulate the patient's life during the fourteen hours when he is not at work, you can very often get him well. If he has a sleeping-porch, you are sure that he is out of doors a good part of this time. I do not believe in forced feeding or in over-feeding. Most of the stomach symptoms are due to this.

Dr. Henry F. Stoll, Hartford: There are a good many people who can work, and get well from tuberculosis; and a good many people who can play, and get well; but very few who can both work and play, and get well. If the patients will go to bed at half-past seven, a good many will get well and stay well under home treatment. With private patients, you can get extremely good results with tuberculin. It relieves the toxic symptoms, and that is a great help. Patients that take tuberculin relapse less frequently and live longer than those that do not take tuberculin; but great harm can be done, if it is not used properly.

Dr. I. E. Brainard, Wallingford: The handkerchief that is held before the patient's mouth when he coughs should be well taken care of afterward, and not stuffed into his pocket with damp sputum on it.

Dr. Erastus P. Swasey, Hartford: Outdoor treatment is not possible in our part of the country in certain seasons. In March we had high winds, and the atmosphere was filled with dust. A great many persons, unless especially instructed, would keep the patients outside in such weather, thinking it was beneficial for them.

Dr. Deming: The matter of climate and location must be taken into consideration; but one of the greatest advantages of keeping the patient out of doors, even when it injures him, is the decreased risk of exposure to the other members of the family. A piece of gauze, sufficiently thick not to wet through, is better than a handkerchief, as it can be burned.

SOME FEATURES OF RECTAL ALIMENTATION.

Dr. Louis M. Gompertz, New Haven: There is a wide difference of opinion among investigators as to the absorptive power of the rectum. In some experiments that I conducted in order to determine this point, I found salt to be absorbed almost as completely as when given by the mouth. Dextrose was either completely absorbed or was made to disappear through fermentation. As all authorities agree that there is practically no absorption of fat from the rectum, no experiments in this direction were made. If nutrient enemata do not reach the small intestine, proteins not predigested, when injected into the rectum, simply putrefy in the large intestine and pass out with the feces. Of the carbohydrates, dextrose was selected because the bulk of carbohydrate food reaches the blood as dextrose. If absorbed in sufficient quantity, it would take the place of protein. From these experiments, it was evident that only a little over one third the necessary amount of calories to sustain the body at rest was daily furnished by the dextrose solutions. Although the experiments were limited to the use of water, sodium chloride and dextrose solutions, we must conclude that the rectum is capable of absorbing these in the form of rectal enemata; furthermore, that such substances, when absorbed, are helpful in nourishing the body and in supplying fluids and salts to the tissues. Therefore, I consider rectal enemata as useful in sustaining the body in emergency circumstances, preventing complete starvation for a short period.

DISCUSSION.

Dr. Lafayette B. Mendel, New Haven: The earlier favorable impressions of rectal feeding have largely been replaced by a skeptical attitude on the part of clinicians, and properly so. Our knowledge of the physiology of the alimentary tract has been greatly extended. It ought, therefore, to be possible to introduce anew such features of rectal alimentation as are promising in principle and susceptible of clinical application. Observations like these emphasize the helpfulness that comes from being able to measure in some way the results that any therapeutic procedure can accomplish.

Dr. Charles J. Foote, New Haven: A nutrient enema is a makeshift, designed to meet an emergency, and cannot be continued for any length of time. It is not intended to furnish proteid or build up the body, but merely to furnish heat and energy and to prevent retrogression. This can be done by using dextrose in the enema. Dextrose is absorbed rapidly and furnishes energy; proteid is absorbed less rapidly and does not furnish energy so quickly. I cannot, therefore, see the advantage of using it, even when predigested. Alcohol fills very much the same place as dextrose. As for the absorption of salt, we should be on our guard in certain cases. I have seen instances in which saline was taken readily in cases of uremia, and large quantities were given; but, at the same time, there was a small excretion of urine, so that a great deal was retained in the system. The patient, in such circumstances, becomes waterlogged and develops edema of the lungs.

Dr. Frank P. Underhill, New Haven: Most of the physicians with whom I have talked seem to think that because we cannot supply the entire 1800 calories, there is no use in employing rectal feeding. I think, however, that it is much better to give half a loaf than to give none. Under the conditions that I have worked with, the carbohydrate rectal feeding has been very successful.

Dr. Walter L. Barber, Waterbury: On one occasion, my wife could retain nothing on her stomach but water. For over a week I kept her up on rectal alimentation, using milk, beef-juice, whiskey and quinine. I do not know whether the rectum received these or the lower intestines, but she recovered.

Dr. J. F. Caley, Middletown: I believe that in cases of the vomiting of pregnancy of the severe type,

there is, more than is usually apparent in any other disease, a reversed peristalsis which may carry rectal alimentation more readily to the stomach than in any other case, for I am sure that in one case that I had, a very small portion of milk was carried up into the stomach.

Dr. Elias Pratt, Torrington: I should like to ask Dr. Gompertz to state whether he has made any experiment with predigested protein in connection with the dextrose.

Dr. Gustavus Eliot, New Haven: You have all had experience with the difficulty in getting these enemata retained in some cases. It seems a very useful preparation to have the milk partly peptonized by the addition of bicarbonate of soda and extract of pancreas. I have used this, at times, with beneficial results.

Dr. Gompertz: I have given predigested protein in days gone by, but have had no analysis of the feces made in these cases, so I do not know whether these enemata were absorbed or not. Patients can live for weeks with only water by rectum, but they are in the beginning stage of starvation, as they live on the tissues themselves. As no accurate measurements were made in the case that Dr. Barber spoke of, I think it very doubtful whether any nutrition was furnished by the milk. With the dextrose solutions, we were able to supply nutrients.

CHRONIC FAMILY JAUNDICE.

Dr. Wilder Tileston, New Haven: The disease is characterized by chronic icterus, of moderate intensity, with enlargement of the spleen and anemia. It is usually hereditary; less often familial or acquired. Males and females are affected with equal frequency. The jaundice is of the non-obstructive type, with well-colored stools and absence of bile in the urine. There is usually a marked urobilinuria. The blood shows the presence of bilirubin and a considerable degree of anemia of the secondary type. The spleen is markedly enlarged; the liver, only slightly so. The patients suffer frequently with "bilious attacks," gallstone colic and nose-bleed, but are otherwise fairly healthy and often live to a good old age. The red corpuscles are abnormally fragile and readily destroyed; hence, the anemia and an increased formation of bile pigment from the hemoglobin thus set free. This leads to the icterus, which is pleiochromatic in origin. The prognosis is good for life; absolutely bad for recovery. Treatment should be confined to general hygiene. Iron may be tried for the anemia. The presence of colic is an indication for the operative removal of the gallstones. I have reports of 13 cases, occurring in four families.

DISCUSSION.

Dr. George Blumer, New Haven: When the patients are first seen at night, they ought to be seen again in the daytime in order to make out the jaundice. I should like to ask Dr. Tileston whether he has seen any suggestion of a relation between this disease and paroxysmal hemoglobinuria, another disease in which there is excessive fragility of the red blood corpuscles.

So far as I know, although other varieties of hemolytic jaundice have been described, there is no statement to the effect that there is an absence of bile in the urine in these other forms. Another point that might cause confusion is the so-called Gaucher's disease, in which there is family enlargement of the spleen, but not usually associated with jaundice. It is interesting to consider whether, if there were actual obstruction from gallstones, as well as the other type of jaundice, the urine would contain bile. One other point that should be emphasized is not to remove the spleen in such cases.

Dr. Tileston: There was one case in which there was a condition of paroxysmal hemoglobinuria associated with the family jaundice, but there is not a very close relationship between the two diseases. Regarding the absence of bile in the urine in other types of hemolytic jaundice, there was usually no bile, but only urobilin, although in some cases there was a small amount of bile. Eleven of the twelve reported instances of Gaucher's disease were in females, so it would be unlikely to have been Gaucher's disease in our cases. When the patients get obstruction with gallstones, they also get bile in the urine, with increase of jaundice.

PERIODIC ATTACKS OF INDIGESTION IN CHILDREN.

Dr. Walter G. Murphy, East Hartford: Diacetic acid is one of the highest chemical compounds associated with acetone, and is the result of intestinal decomposition of food. Various theories have been suggested associating diacetic acid with cyclic vomiting and recurrent attacks of indigestion. The exciting causes of the attacks of vomiting are fright, excitement, fatigue, anger, exposure to cold and similar influences acting through the nervous system. Many argue, also, that the attacks are not due to errors in diet. Acetone may be present in other conditions, and the neurotic and rheumatic aspects must be recognized as contributing causes. The condition is, I believe, a neurosis, toxic in character, based upon a defective nervous control, the result of an inherited, unstable and irritated nervous system. If this idea is correct, treatment should be directed to the cause and not to the result. Most of the children are neurotic and anemic. On account of their digestive troubles, they are often underfed. A full and generous diet should be given them, and general care of the hygienic conditions. On the appearance of symptoms of an attack, stop food and thoroughly clean out the digestive tract with castor oil, and give repeated doses of sodium bicarbonate.

DISCUSSION.

Dr. Frank P. Underhill, New Haven: There is little doubt that the symptoms described by Dr. Murphy are dependent on defective nervous control. It is well known that a child is much more easily put into a condition of defective nervous regulation than is an adult. Excessive putrefaction in the intestine may serve as a stimulus in these neurotic and undernourished subjects. I do not think that the presence of diacetic acid in the urine in these cases should be over-emphasized. Acetone bodies probably arise within the body as the result of the incomplete combustion of fats. I believe that diacetic acid is neither the cause nor the direct result of the pathological condition under discussion; indeed, I should ascribe the presence of this substance in the urine to the condition that accompanies the abnormal manifestation, viz., the under-nutrition, in which it may be easily demonstrated that diacetic acid is always present. Young children are thrown into a condition of acidosis with extreme ease, and a moderate degree of acidosis, especially in children, should not be regarded as a grave symptom.

Dr. Charles A. Goodrich, Hartford: We should also bear in mind certain intestinal disorders in children in which there is, besides cyclic vomiting and convulsions, a certain nervous phenomenon resembling the beginning of diabetic coma in adults. These cases should be included in considering this matter. Inas-

much as in a good many cases the diet apparently does not influence the attacks, these children become increasingly malnutrient. The suggestion of such a simple clinical test as a considerable aid in certain of these intestinal disturbances, and also the point of considering the patients' well-being between these attacks, are of great value.

THE RELATIVE VALUE OF SYMPTOMS, PHYSICAL SIGNS, TUBERCULIN AND THE X-RAY IN THE DIAGNOSIS OF TUBERCULOSIS.

DR. HENRY F. STOLL, Hartford: In tuberculin, we have a diagnostic aid of accepted value if used in conjunction with the symptoms and physical signs. The x-ray is of a great deal of assistance in the diagnosis of pulmonary conditions. The negative must not only be perfect, but the interpretation thereof is of value only when made by one who has had a large experience in this particular field, as it is the most difficult of all x-ray work. Incipient cases that have been carefully examined come to post-mortem but rarely, and much more can be learned by a comparison of the physical signs and the x-ray findings in a series of early cases than by the autopsies of advanced cases. There is no better way to ascertain one's diagnostic ability or limitations than to compare the physical signs in one's cases with the x-ray plate. In deep-seated lesions, especially of the lower two thirds of the lung, the x-ray will sometimes demonstrate a lesion that does not give physical signs. When the involvement is slight, it may be necessary to make several plates before a diagnosis can be given. If we are to detect incipient tuberculosis, we must inspect, palpate, percuss and auscultate our patients. We must also question them at length. An incomplete examination gives the patient an unwarranted sense of security.

DISCUSSION.

DR. WILLIAM B. BARTLETT, Hartford: There is a great difference between clinical tuberculosis and anatomical tuberculosis. The relative value of symptoms, physical signs, tuberculin and the x-ray is very different in the two forms of the disease. It is, however, with the diagnosis of clinical tuberculosis that we are concerned. Physical signs, tuberculin and the x-ray, if without symptoms, may all three be disregarded; with symptoms, the diagnosis of tuberculosis may be made, even though signs, the x-ray and the tuberculin test are negative. When obtainable, the history of exposure to infection from some tuberculous relative or friend is important. It is, however, surprising how seldom such a history can be obtained. The importance of malaria in the past history should be emphasized. Among symptoms, pain is very important. I should like to add to Dr. Stoll's statement that râles at the apex may be due to other causes the statement that râles at the base most frequently are due to other causes. A positive tuberculin reaction does not mean clinical tuberculosis. Notwithstanding the many new and simple tests with tuberculin that have been introduced, we are gradually coming back to a dependence upon the subcutaneous method as the most reliable, and even this may occasionally be at fault.

DR. DAVID R. LYMAN, Wallingford: Dr. Stoll's comparison of the relative value of these four means of diagnosis shows that not one of them is of such supreme value that we can afford to leave everything else out of consideration. About the only thing that he did not mention was the constant occurrence of little localized dry pleurisies in the chest in these cases. Tuberculin is one of the most powerful poisons that we have. I have never seen ill-effects from its subcutaneous use in small doses. I do not, however, think it necessary to employ it, if you have made your diagnosis without it and the patient is willing to accept your opinion and act upon it. I have never felt like using the eye test when I could use the subcutaneous test, which is free from danger. I do not think that there is any question but that an expert can discover with the x-ray deep-seated lesions that an ordinary person would miss.

DR. F. S. CROSSFIELD, Hartford: On behalf of the laryngologist, I would say that in the early stages of pulmonary tuberculosis there are no absolutely pathognomonic symptoms in the larynx.

DR. J. B. GRIGGS, Hartford: While the positive tuberculin test is not valuable, the negative test is. The negative test is particularly valuable in adults, while the positive test is of value in children.

DR. STOLL: As I said in my paper, if the tuberculin test is negative, the possibility of the presence of tuberculosis is very slight, but it does not exclude the disease. Long before the stethoscope was invented, and purely and solely by means of the symptoms, physicians diagnosed tuberculosis. After a careful history has been obtained, it is unusual to have the physical signs not agree with the diagnosis made from the history and the symptoms.

The President's annual address was delivered by DR. SAMUEL D. GILBERT, of New Haven.

The following officers were elected to serve for the ensuing year: President, Dr. Frank K. Hallock, of Cromwell; Vice-Presidents, Dr. Edmund P. Douglass, Groton, and Dr. E. T. Bradstreet, Meriden; Secretary, Dr. Walter R. Steiner, Hartford; Treasurer, Dr. Joseph H. Townsend, New Haven.

The Society will meet next year at Hartford, on the fourth Wednesday and Thursday in May.

Book Reviews.

The Health of the City. By HOLLIS GODFREY. Boston and New York: Houghton, Mifflin Company. 1910.

This volume is a collection and expansion of a series of eight essays on familiar topics of public hygiene published during the past four years in *The Atlantic Monthly*, to which are added two chapters on city housing abroad and in America, presenting the result of personal investigation by the author in Europe and in the Unites States. The subjects of air, milk-supply, food, water, sewage, ice, plumbing and noise are successively considered in non-technical, emphatic form such as should carry the important points of these problems home to the intelligent lay citizen interested in the hygienic welfare of his family and of the community. Mr. Godfrey's position as head of the department of science of the Mechanics Arts High School in Boston has given him first-hand opportunity of studying and teaching the application of the sciences to the concrete necessities of domestic and municipal life; and his professional training as a chemist affords him the technical knowledge essential to

reliable popular scientific writing. The book closes with a useful selected bibliography on the subjects under consideration.

A Synopsis of Surgery. By Ernest W. Hey Groves, M.S., M.D., B.Sc. Lond., F.R.C.S. Eng., Assistant Surgeon to the British General Hospital; Surgeon to the Cossham Hospital; Senior Demonstrator of Anatomy at the Bristol University. Second edition, revised and illustrated. New York: William Wood & Co. 1910.

It is too bad, in these days of Carnegie reports on medical education, that synopses of surgery, or of any other great scientific subject, should still find favor with serious teachers and students.

Clinical Obstetrics. By Robert Jardine, M.D. Edin., Professor of Midwifery in St. Mungo's College, Glasgow. With 108 illustrations, 4 colored plates. Third edition. New York: William Wood & Co. 1910.

This book has reached its third edition in England and now is published here in America. The author has departed much from the usual form of obstetrical textbooks, and in the reviewer's opinion it is of no marked advantage. The clinical histories many times lack the exactness which is so necessary for the complete understanding of these cases. There are many statements with which the obstetricians of this country will not agree. The author's reasons for them are not convincing. His advice to scrub the hands and forearms carefully and then soak them in an antiseptic for several minutes simply for the external examination of the patient (palpation and auscultation), followed a few pages later by the remark that the use of rubber gloves is not necessary and that he prefers bare hands, is a fair example of the statements he makes. Another is one on page 537, where he says sewer gas caused a temperature of 103° though the treatment was intra-uterine douches, the patient later developing a phlebitis. Three years later the same patient, he says, was again confined in the same house, and as there was no escape of sewer gas she made a normal convalescence! His last chapter, on infant feeding, is most crude and superficial and either should be eliminated entirely or rewritten in a future edition. The reviewer cannot see that this book will fill any gap in the American obstetrical textbooks of to-day. From the bookmaker's point of view it is an excellent production.

The Pathology of the Living and Other Essays. By B. G. A. Moynihan, M.S. Lond., F.R.C.S. Leeds. Philadelphia and London: W. B. Saunders Company. 1910.

Moynihan has collected into a convenient little book of some 260 pages a series of nine admirable occasional addresses. Much of what he says here he has said before in other writings, but these collected essays are pleasant, suggestive and effectively combined. They are well worth reading.

Living Anatomy and Pathology. The Diagnosis of Diseases in Early Life by the Roentgen Method. By Thomas Morgan Rotch, M.D. Three hundred and three illustrations. Philadelphia and London: J. B. Lippincott Company. 1910.

This new work by Dr. Rotch is a contribution of great value to the science of pediatrics, as an exposition of the methods of application of the x-ray to the diagnosis of diseases in early life. After an introduction on the general principles of interpretation of x-ray plates, and a description of living normal anatomy as illustrated by them, the author expounds his theory of anatomic age, and then proceeds to a systematic regional consideration of the diseases whose diagnosis may be facilitated or made perfect by means of the Roentgenogram. This study is profusely illustrated by 303 figures, comprising 264 full-page plates, composing a series of Roentgen pictures of unsurpassed excellence, the credit for which belongs to Dr. Arial W. George, by whom they were taken. These plates, with the accompanying legends, complete the purpose of the admirable text and help to make the volume not only illuminating, but of unique merit.

A Practical Treatise on Fractures and Dislocations. By Lewis A. Stimson, B.A., M.D., LL.D. Yalen., Professor of Surgery in Cornell University Medical College, New York; Surgeon to the New York and Hudson St. Hospitals; Consulting Surgeon to Bellevue, St. John's and Christ Hospitals; Corresponding Member of the Société de Chirurgie of Paris. Sixth edition, revised and enlarged. With 361 illustrations and 65 plates in monotint. New York and Philadelphia: Lea & Febiger. 1910.

Stimson's book is a pleasant and discursive book; it should be far more generally owned and read, for it does more than present the subject of treatment only in dreary detail. We wish it were better illustrated. This sixth edition has some additional matter, the results of the author's studies on injuries of the carpus and tarsus and on midcarpal fracture-dislocations. The author has added sections on fractures of the floor of the acetabulum also, and of the internal epicondyle of the femur and on backward dislocation of the lower jaw. Stimson's work continues to be the best work of its kind known to us in English.

Studies on Immunization and Their Application to Diagnoses and Treatment of Bacterial Infections. By Sir A. E. Wright. Octavo. Pp. xv, 489. William Wood & Co. 1910.

This book has already been reviewed in these columns (1910, clxii, 330) as published in London by Archibald Constable & Co. The American edition differs in no respect from the English edition of last year.

Prevention and Treatment of Abortion. By Frederick J. Taussig, M.D., Lecturer in Gynecology, Medical Department, Washington University. Fifty-nine illustrations. Pp. 179. St. Louis: C. B. Mosby & Co. 1910.

Taussig is to be congratulated on having written such an interesting and excellent work. The book consists of three parts with an appendix. The first part is taken up mainly with general considerations and statistics of abortion, pathology, etiology, symptoms, diagnosis and prognosis. The second part deals entirely with the prevention of abortion. The final part deals with the treatment and operative technic. All aspects of abortion are fully and adequately treated. The rules Taussig lays down for the treatment of abortion are conservative, but as he is writing to guide the general practitioner, such treatment is much the wiser course to pursue. His descriptions of the instruments used and the operative technic is excellent. For the general practitioner it will prove a book of immense service and to the specialist there is much that will help him. The book is well illustrated by diagrams and photographs and it should have a wide sale.

An Outline of Individual Study. By G. E. Partridge, Ph.D., formerly Lecturer in Clark University. New York: Sturgis & Walton Co. 1910.

This volume presents an outline of pedagogic methods in the study of individual characteristics in children. After an introduction on the history and theory of individual study, a careful exposition and illustration is given of the simpler, practical procedures for prosecuting such study in the class room. Psychologic tests are for the most part little employed, but reliance is placed on direct observation of physical, mental and moral qualities. As might be expected, the book is weakest in its medical aspects, and betrays the attitude of one who knows something about medicine, but is not at home with it as a science. Nevertheless, it is an interesting and useful manual for such as are concerned with the education of children, in which it is coming to be realized that means must more and more be adapted to specialized needs and that for the best results to himself and the community, the child should have his variations studied and encouraged or repressed, and should be treated and trained not as a unit, but as an individual.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, AUGUST 18, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 Tremont Street, Boston, Mass.

A COMMUNITY'S WASTE.

The two-years' controversy in the United States Supreme Court between the National Government and the state of New Jersey, over the discharge of Passaic Valley sewage into New York Bay, has been settled by this State's concession of all the important Federal requirements for the protection of navigation, and for the preservation of the purity of the great body of water in question. The agreement reached provides for the most extensive plans of sewage treatment that have as yet been projected in the United States. After passing through coarse screens, grit and sedimentation basins, etc., the sewage will be pumped under pressure through a tunnel to a point in the Bay, for disposal through a series of outlets.

This judicial proceeding will surely have far reaching consequences for the future of American national sanitation; it should serve for a precedent establishing that hereafter, as a principle of law, no commonwealth nor any community can (unless it first be rendered innocuous) burden an adjacent community with sewage. And it is most gratifying to note, in these premises, that applications made by cities in New York State to the State Department of Health for the necessary approval of sewage plans, are repeatedly being denied, pending measures to be taken by these municipalities for making their sewage harmless beyond their borders. In that state, under the able Commissionership of Dr. Eugene H. Porter, the Department's consistent movement during several years past to protect national water courses from undue pollution, is rapidly gaining from its citizens the active support and co-operation it so eminently deserves.

The *Journal of the American Medical Association* very pertinently observes that the disposal of a city's waste has a most important bearing on disease; any city's waste products should, in behalf of its own citizens, be made innocuous. An American city of half a million population has some 300,000 tons of refuse of all kinds (garbage, swill, ashes and miscellaneous rubbish) that is, about three tons per annum for a family of five. Boards of Health are indeed justified in formulating the strictest regulations concerning the handling of such material — fermenting, decomposing, malodorous masses, food for rats and other disease-breeding vermin, breeding places for flies and other infection-spreading insects.

Since the treatment and collection of garbage in the household are even more important for sanitation than its ultimate disposal, housekeepers must keep their kitchen refuse in tightly covered cans, which should be emptied at least daily and scalded frequently. A garbage-can is thoroughly disinfected by burning it out with old paper.

The municipal collecting-cart should be carefully-covered and water-tight; metallic carts now generally prevail to the exclusion of the old, disgraceful, leaking and reeking wooden vehicle. The employees are now the decently-appearing and self-respecting "white wings" or "brown wings."

Incineration is unsatisfactory, and a nuisance that has been abandoned as intolerable in about half of the 225 American communities in which it has been tried. The chief reason of this failure is the low temperatures at which the garbage has been burned. British and Continental cities have been more successful because they have burned garbage at a high temperature (above 1,250 F.) under forced draft. No neighbors have complained of this system, which fact is peculiarly advantageous in that these "destructors," being unobjectionable, are placed in the municipal interior, thus shortening the haul and diminishing the cost. In the English "destructor" the ashes and garbage are burned together: thus collection is simplified, the ashes absorb the moisture from the swill, a process of desiccation which retards or restrains fermentation; whilst on the other hand the moisture from the swill wets the ashes and prevents them from blowing about. The resultant ash is mostly vitreous clinker, splendid material for filling, paving or concrete.

Again, the caloric value of mixed garbage and ashes is enormous; and the best may be used for civic purposes, such "destructors" are now successfully operated in at least three American communities — New Brighton, Staten Island, N. Y., Seattle, Washington and Milwaukee, Wis. (the largest of its kind); and in two Canadian cities — Montreal and Vancouver, B. C. Cleveland and Columbus, Ohio, use the "reduction" method, which yields a profit from the grease and the tankage — the latter being a valuable fertilizer. About five per cent. of garbage may readily be extracted in the form of grease: the remaining refuse, consisting largely of paper, cardboard, twine, boxes, wood, old shoes, rubbers, rags, tin cans, and bottles, has all a market value; about 90 per cent. of such waste may be reclaimed for commercial purposes.

THE POLIOMYELITIS SITUATION.

We publish in another column a resolution of the American Orthopedic and Pediatric Associations regarding means of investigating and combating the spread of poliomyelitis. It is certainly advisable that the suggestion contained in this action should be widely and conscientiously followed. Evidence is rapidly accumulating, unwelcome as it may be, that poliomyelitis is becoming endemic in certain rather widely separated portions of the country, and also that it is increasingly appearing in epidemic form. Not many years ago the affection was little known by the profession at large, for the reason that it was rarely met and recognized by general practitioners: it should not, however, be supposed that its increase has been proportional to the general interest it has excited. Undoubtedly, many cases formerly ran their course undiagnosticated, just as many now are diagnosticated, which the sequel shows to be a totally different infection. From the most conservative standpoint, however, it cannot be denied that the disease, especially in its epidemic form, has increased within the past few years. Unfortunate as this may be, it has at least served to stimulate investigation, which has already proved fruitful and which is sure to lead to more definite results in the future.

We now know, through the researches of Flexner, Lewis and others, that the disease is due to an infection, and that it is presumably very mildly communicable. Nothing definite is known of its epidemiology, and the treatment as yet remains empirical. In view of these facts a very grave

responsibility naturally rests upon all physicians and particularly upon those, who are the appointed guardians of the public health. It is no doubt wiser to err on the side of safety, than of laxity in the handling of epidemics, such, for example, as has recently visited Springfield in this state. Physicians who are in contact with early cases of the disease should take certain precautions in regard to changes of clothes and disinfection. Certainly a modified quarantine should be enforced, and every possible means taken to trace the source of the disease in its inception and in its possible transmission from person to person. All of these things and others of similar sort should be done, in the hope that some added light may be thrown upon the obscure etiological problem. We, therefore, heartily commend the attitude of the committee to which we have referred, in promulgating a policy of investigation which will leave no stone unturned, in the effort to disclose the secret of this strange malady.

A word of warning, however, may not be out of place against permitting a feeling of panic to develop, which the facts do not in any way justify. Few situations have arisen in late years demanding so high a degree of judgment, on the one hand to provide for the utmost safety of the community, and on the other to prevent an undue anxiety always detrimental to the public health. We must await, with what patience is possible, the decision as to the degree of communicability of the disease. In the meantime there should be comfort in the fact that the evidence heretofore is largely against the theory of direct transmission, except under certain peculiarly favoring, but as yet unknown, conditions.

AMERICAN ASSOCIATION FOR THE STUDY AND PREVENTION OF INFANTILE MORTALITY.

A meeting of this association will be held in Baltimore from Nov. 9 to 11 of this year. The objects of the association are to study the problem of infant mortality in all its relations, to disseminate knowledge concerning the causes and prevention of this mortality and to encourage methods of prevention. Previous investigation has been sufficiently encouraging to render it probable that if a large and representative body of persons can approach the question in a comprehensive spirit a very great reduction in the death rate of infants might be secured. As the prospectus of the forthcoming meeting states, "The blame in the present situation has shifted to society and to social conditions." The solution, therefore, must be undertaken by a broadly conceived movement regarding the matter from varied standpoints. This the association has attempted to do by dividing the subject matter under discussion into various sections. At the coming meeting for example, Dr. W. H. Welch of Baltimore is to preside over the section on municipal, state and federal prevention, Dr. L. Emmet Holt over medical prevention, Dr. Helen C. Putnam over the section on educational prevention and Dr. Hastings H. Hart, Director of the Department of General Helping of the Russell Sage Foundation over the section on philanthropic prevention. An exhibition is also to be held in connection with the meeting in accordance with the well recognized principle that what may be definitely seen is often of more educational value than that which is merely heard. This society should have a large membership and should by degrees enlist the interests of most varied classes in the community. By this means alone, which should be somewhat readily attainable, a campaign of education may be initiated which will go far toward reducing the present appalling and unnecessary infant mortality.

MEDICAL NOTES.

Death of Florence Nightingale. — Florence Nightingale died in London on Aug. 13, at the age of ninety. Extended notice of her life and work will follow in a later issue.

Sleeping Sickness. — It is reported through Bordeaux that sleeping sickness has gained a foothold in certain regions heretofore uninfected in equatorial Africa.

Cholera in Russia. — Cholera has reached alarming proportions in Russia as shown by the fact that the estimated death list for 1910 is about 57,000, as compared with 28,000 in 1909, and still fewer in 1908.

The epidemic has appeared not only in the larger cities, but also in remote districts which adds to the difficulty of its control. Germany has taken precautions against its spread across the frontier.

The Late Dr. F. A. Hesler. — According to correspondence recently made public, it appears

that the memory of the late Dr. Frederic A. Hesler, of the United States Navy, has been honored by the citizens of Guam in recognition of his admirable work in sanitation while stationed in that island.

Dr. Hesler worked particularly for the segregation of lepers and the establishment of a leper colony. He also initiated the building of the first hospital in one of the provinces.

Suicide. — A recent statistical investigation appears to show that suicide is increasing in the United States. The number of persons dying by their own hands in 1909 is estimated as 12,500. In general, there has been a steady increase in the number of cases since 1890.

Figures for certain of the Massachusetts cities in 1909 are as follows: Boston, 124; Springfield, 15; Worcester, 10; Holyoke, 10; Lowell, 18; Lawrence, 9; various smaller cities, 8 or less.

Precautions Against Cholera. — By order of the Public Health Service, American Consuls in the large European ports are detaining for five days prior to sailing, those emigrants who come from the cholera-infested districts of Russia. Even cabin passengers who cannot show that they have not been exposed are detained, and all baggage is being disinfected. The ease with which communicable diseases are passed along among the emigrants is shown by the fact that on the slower steamers, west bound, measles appears on practically every trip on the eighth or ninth day. The steerage passengers so afflicted contract the disease, as the doctor on one of the liners explained, during the railroad journey previous to embarkation.

The Investigation of Epidemic Poliomyelitis. — At the recent meeting of the Congress of American Physicians and Surgeons held in Washington in May, 1910, a joint session of the American Orthopedic and American Pediatric Societies was held and the subject of epidemic poliomyelitis was discussed. The following resolution was adopted:

"It having been shown by recent epidemics and investigations connected with the same that epidemic of infantile spinal paralysis is an infectious communicable disease that has a mortality of from 5 to 20%, and that 75% or more of the patients surviving are permanently crippled, state boards of health and other health authorities are urged to adopt the same or similar measures as are already adopted and enforced in Massachusetts for ascertaining the modes of origin and manner of distribution of the disease with a view of controlling and limiting the spread of so serious an affection."

A committee with Dr. Robert W. Lovett, president, Boston, Mass., Dr. Irving M. Snow, secretary, Buffalo, N. Y., was appointed to urge the various state and municipal health authorities to take up the work of investigation of the various foci of epidemic poliomyelitis, to study its epidemiology and to instruct the public that the disease is at least mildly communicable.

Boston Milk Fund. — During the hot months of summer the capacity of the Boston Hospitals, including the Floating Hospital is not sufficient to provide for the needs of the sick babies of the city. The Milk Fund has cared for 125 babies up to this time, but further support is needed if this work is to continue during the remainder of the summer. By means of this fund many babies may be saved who would otherwise die for lack of proper hospital treatment.

An Appreciation of Medical Investigators. — In the British House of Commons, June 29, Colonel Seeley, under-secretary for the colonies, mentioned appreciatively the heroism of the investigators of sleeping-sickness, especially of Sir David Bruce, who had gone with his wife into the heart of the disease-ridden section where nearly every one was sick and no patient recovered. There were many other investigators, some of whom had succumbed in their efforts to find out the cause and remedy for the plague. Colonel Seeley said that when the history should be written of what had been done by these brave men it would perhaps be considered "as giving more striking proof of the ability of men to overcome natural fear than almost anything else in the annals of mankind." It is pleasing to see such recognition of the heroism of medical men from high official sources. Such deeds are not done under the excitement of battle. The risks are deliberately taken for human good and the danger fully appreciated, but too seldom are they thus publicly honored. — *Journal of American Medical Association.*

The Harvey Society Lectures. — At a meeting of the Harvey Society held in April, 1910, the following officers were elected for the year 1910–1911: President, Dr. Simon Flexner; Vice-President, Dr. John Howland; Treasurer, Dr. Edward K. Dunham; Secretary, Dr. Haven Emerson; Council, Drs. Graham Lusk, S. J. Meltzer, and James Ewing.

The following program for the next series of lectures has been arranged for:

Oct. 15, 1910: Prof. Dr. H. Chiari, of Strassburg, Germany, on "Die Bedeutung der pathologischen Autopsie und sonstiger pathologisch-anatomischen Untersuchungen."

Nov. 12, 1910: Prof. W. E. Castle, of Harvard University, on "Unit Characters in Heredity."

Dec. 10, 1910: Prof. Harvey Cushing, of Johns Hopkins University, on "Certain Clinical Aspects of Dyspituitarism."

Jan. 14, 1911: Prof. Arthur R. Cushny, of the University of London. (Subject to be announced later.)

Feb. 4, 1911: Dr. Thomas B. Osborne, of the Connecticut Agricultural Experiment Station, New Haven, on "The Chemistry of the Proteins."

Feb. 25, 1911: Prof. Jacques Loeb, of the Rockefeller Institute for Medical Research. (Subject to be announced later.)

March 18, 1911: Prof. H. Gideon Wells, of the University of Chicago.

These lectures are open to the public and are given on Saturday evenings at the New York Academy of Medicine.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston.— For the week ending at noon, Aug. 16, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 35, scarlatina 14, typhoid fever 19, measles 19, smallpox 0, tuberculosis 94.

The death-rate of the reported deaths for the week ending Aug. 16, 1910, was 17.80.

Boston Mortality Statistics. —The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Aug. 13, 1910, was 190, against 221 the corresponding week of last year, showing a decrease of 31 deaths and making the death-rate for the week 15.73. Of this number 96 were males and 94 were females; 188 were white and 2 colored; 127 were born in the United States, 62 in foreign countries and 1 unknown; 31 were of American parentage, 126 of foreign parentage and 33 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 32 cases and 2 deaths; scarlatina, 23 cases and 2 deaths; typhoid fever, 18 cases and 1 death; measles, 22 cases and 1 death; tuberculosis, 102 cases and 13 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 6, whooping cough 1, heart disease 12, bronchitis 2. There were 7 deaths from violent causes. The number of children who died under one year was 69; the number under five years, 87. The number of persons who died over sixty years of age was 44. The deaths in public institutions were 91.

Cerebrospinal meningitis, 1 case. Anterior poliomyelitis, 5 cases and 2 deaths.

Of the above infectious diseases the following were non-residents: Consumption, 4 cases. Diphtheria, 1 case and 1 death. Typhoid fever, 1 case

Deducting deaths of non-residents, the total is 166 and the death-rate is then 13.74.

Typhoid Fever in Worcester, Mass. — It is reported that up to Aug. 14, about forty-five cases of typhoid fever had appeared in Worcester, presumably as a result of infected milk.

Nurses' Home for the Quincy, Mass., Hospital. — Mr. Henry M. Faxon has given money for the erection of a Nurses' Home in connection with the Quincy City Hospital. There has long been need for such a building, which is now for the first time rendered possible by Mr. Faxon's gift. The estimated cost is about $15,000. It is proposed to erect a building of brick, with accommodations for twenty nurses. Other improvements are also to be made on the hospital grounds.

NEW YORK.

Advisory Executive Committee for Health Department. — The State Commissioner of Health has named the following experts as an Executive Committee of medical officers to act in an advisory capacity to the Health Department: Drs. F. C. Curtis, of Albany; Edward Clark, of Buffalo; F. D. Earl, of Ogdensburgh; W. B. Gibson, of Huntington; A. D. Lake, of Gowanda; D. C. Moriarta, of Saratoga Springs; Joseph Roby, of Rochester; D. M. Totman, of Syracuse. From the first of August to the end of the year two laboratory courses at the State Hygienic Laboratory in Albany are offered to the health officers of the state every week. One of these is devoted to sanitary water analysis, and every health officer is invited to attend either course, or both, if possible. By an act of the last legislature a deputy commissioner of health was provided for, and the commissioner has appointed Dr. William A. Howe to that position. For fifteen years Dr. Howe has been medical officer of the town of Phelps, in Ontario County, and during the past year has served as director of the Division of Communicable Diseases of the State Department of Health.

2. Solis-Cohen and Strickler studied the leucocytes in a large number of consumptives. They found that the total white count was highest (a high normal) in cases which were improving. In incipient and moderately advanced cases, and in improving cases, the percentage of lymphocytes was greatest and that of polynuclears least. The percentage of eosinophiles was greatest in incipient cases and least in moderately advanced cases. Large mononuclear and transitional cells were most numerous in incipient cases and in cases which were improving.

1. Clarke emphasizes the fact that developmental anomalies are at the bottom of many cases of chronic constipation; posture is frequently a result rather than a cause of this ptosis; congenital potential factors are present in many individuals which become active through accident, such as traumatism, rapid and badly cared-for childbirth, habitual constipation, operative adhesions, etc.; neurasthenia often dates from childhood or puberty; operation, therefore, in the adult may give only partial relief; various suspension operations are valuable in properly selected cases, but disappointing in the remainder; at best, these fixation points may be unstable. Radical excision of obstructive portions of the large bowel may give the highest operative mortality, but the best ultimate results in the survivors. A well-taken skiagraph is of the greatest diagnostic value.

2. Lyon and Qualls find from clinical experiments that the preparations cactin and cactina have absolutely no therapeutic effects.

4. Atwood, studying 204 cases of idiocy with the serum tests for syphilis, found it positive in 14.7% of his cases, a high enough percentage to warrant every case of idiocy having a test made to ascertain whether the etiological factor was syphilis.

6. Roy emphasizes epistaxis as one of the first symptoms of nasal diphtheria in many cases. That together with a prolonged irritative nasal discharge is often diagnostic.

9. Madison draws the very vivid picture of that type of case caused by a predominence of the influenza bacillus. These cases are characterized by cough for many months or years, thick, tenacious, mucopurulent sputum, rather profuse, often accompanied over the space of many years by repeated hemorrhages, presence of a diffuse bronchitis and at times bronchiectasis, frequent recurring attacks, often asthmatic seizures and always absence of tubercle bacilli in the sputum or by guinea-pig inoculation. This type of case was found by Lord in 186 cases to be mixed infection, with predominence of the influenza bacillus. The cases are better in the summer, but repeatedly aggravated in the cold or damp weather. They, however, do not differ materially from chronic bronchitis caused by other organisms. They are of greatest importance in their resemblance to tuberculosis, in which many of them differ in no wise except by the absence of tubercle bacilli. Undoubtedly many of them find their way to tuberculosis institutions and there swell the percentage of recoveries. The prognosis in long-standing cases is bad; but the patient may enjoy very good health aside from his bronchitis. Change of climate may cure the shorter cases. Treatment in the majority of cases is of little avail.

11. MacCarty concludes from his analysis that of all appendices removed at operation 23.5% are partially or completely obliterated; the process may be complete at ten years of age; the obliteration does not occur as a physiologic involutionary process, but is dependent on a definite inflammatory reaction. In a series of 2,000 specimens 0.6%, or about 1 in every 175 removed at operation, is malignant. In a series of 5,000, 44%, or about 1 in every 225 is malignant. In a series of 2,000, 2.2%, or about 1 in every 40 partially or completely obliterated appendices is malignant. In a series of 5,000, 1.6%, or about 1 in every 53 partially or completely obliterated appendices, is malignant. Carcinoma of the appendix may occur as early as five years of age and as late as eighty. In this series 77% were not capable of being diagnosed from the gross external appearance. [E. H. R.]

1. Eiselsberg, considering a rapid subcutaneous deposit of fat, a persistence of juvenile type in younger individuals and decrease or loss of genital function in the adult, dependent upon diminished function of the anterior portion of the hypophysis, and gigantism and acromegaly upon increased function of this portion, reports his operative experience with 3 cases of the former type, 2 cases of the latter and 1 case of mixed types. The pathological report of the first 3 cases was epithelial carcinoma, angio-sarcoma and benign cyst; of the second 2 cases, sarcoma and sarcoma or carcinoma; and of the last case, epithelial carcinoma. The first 3 cases have shown decrease in obesity, reappearance of hair and sexual function and improved vision; the second 2 cases (acromegaly) both died of meningitis two and three days after operation; and the last case (mixed type) has shown marked diminution in size of hands, feet and head, reappearance of sexual function and some amelioration of vision. Eiselsberg gives his method of operating. It is essentially Schloffer's. Iodoform gauze is preferred to vioform or isoform gauze as a nasal pack.

2. Mixter and Quackenboss report a case of hypophyseal tumor with infantilism successfully operated upon by Kanaval's method. Nothing but the vomer had to be removed in order to reach the sphenoidal cell. All other parts, including the turbinates, were easily held back with retractors. There have been in three and one half months gradual improvement in vision and increase in weight; sensation of the upper lip is lost and occasionally there is some watery nasal discharge. An exhaustive report of the cyst fluid and tissue from the cyst wall is given by Verhoeff (congenital epithelial tumor with cystoid degeneration) ("congenital epithelioma").

3. Elsberg had used Meltzer's intratracheal insufflation method in three human beings at the time of publication of this communication. The method of introduction of the tube is described. Two assistants are required, — one controls the pressure by the manometer and interrupts the stream every few minutes; the other manages the anesthesia and watches the patient's general condition. Case I was a myasthenia gravis and was kept alive for five hours. Before insufflation, patient was pulseless, deeply cyanosed and unconscious. Within a minute the color was good and pulse appeared at the wrist. Case II was a thoracotomy and aspiration of lung performed by Lilienthal and reported by him in this journal (4); there was immediate cessation of mucus, no cyanosis, excellent pulse, consciousness four minutes after operation. Case III was a rib resection and drainage of pleural cavity.

5. Although the thoracic work of Willy Meyer on human beings has not been brilliant from the viewpoint of recoveries, it is a very valuable contribution on account of many important facts and suggestions which have been developed by a careful analysis of each case in an endeavor to ascertain the causes of imperfect results or failures. He reports 3 cases of acute empyema, 3 of lung abscess and 4 of esophageal cancer. He uses positive differential pressure apparatus. One of the empyema cases was too profoundly septic to be saved. The other two have convinced him of the value of dressings under positive pressure and daily treatments with breathing under pressure. The cases of lung abscess were treated in one instance by incision and drainage and in two by partial pneumectomy. The first died of brain abscess and the other two shortly after the operation. His experience convinces him of the value (1) of superficial anesthesia throughout the operation to enable the patients to expectorate, preferably nitrous oxide and oxygen to minimize cardiac depression; (2) of careful separation of the vagus branches and division perhaps after cocainisation of the vagus as high up in the thorax as possible, rather than crushing or ligation; of preliminary external drainage of abscesses to avoid aspiration. His experience with three exploratory thoracotomies for esophageal cancer has convinced him of the value of the Schede incision for large skin-muscle flap to get the scapula out of the way, incision in third intercostal space for treatment of upper portion and second incision in sixth or seventh spaces for treatment of the lower stump. His experience with one case of esophageal resection for cancer, which died shortly after operation, convinces him that (1) the first step after entering the thorax should be examination of both pneumogastrics; for, if both are inseparably connected with the tumor, resection must be abandoned, and (2) shock is of twofold origin; interference with the system of vagus nerves and their anastomoses with the sympathetics by blunt manipulation and CO_2 accumulation in the blood regardless of the type of differential pressure. To guard against the latter he advises the interposition at regular intervals of brief periods of artificial respiration, allowing the lungs to collapse.

6. Green and Janeway present a new cabinet for anesthetization of thoracic cases (surgical procedures and respiratory embarrassment from morphine, illuminating gas, ether or smoke). The special advantages of their cabinet are portability, inclusion of pump and motor beneath box, and a valve mechanism permitting rhythmic rise and fall of pressure (artificial respiration). The frequency of artificial respirations can be regulated as well as the ratio of duration of inspiration and expiration. Different types of apparatus are discussed. They believe with their cabinet the patient absorbs less ether than with any other. An improved button for esophagogastrostomy is reported, but their recent excellent results with the suture have led them to doubt the advantage of the use of the button for union of resected stomach and esophagus.

7. Janeway and Green demonstrate from an extensive study of statistics the surgical importance of the cardia and necessity of early diagnosis of cancer in this region and the esophagus. They advise the use of the gastroscope, with removal of pieces of growth for examination. After a study of the lymphatics of the stomach they are persuaded that radical operation must mean the resection of most of the lesser curvature and, to be practical, an end-to-end union is necessary. They have had 10 out of 17 dogs recover, 5 of the last 6, but none lived over two months. Death was due to insufficient food passing pylorus on account of loss of propulsive force of stomach and unrelaxing pylorus due to section of the vagus. They have apparently overcome the trouble by incising the pylorus down to the mucosa and suturing as in pyloroplasty. Their operation, which is described and well illustrated, is a resection with end-to-end anastomosis with suture, the stomach being delivered into the thorax through an incision in the diaphragm between the esophagus and left crus.

7. Rywfel, J. H. *Critical Review. Lactic Acid in Metabolism. Part II.*

1. Beddard's patient with ochronosis had used carbolic acid for four years, as a dressing for ulcers of the legs.

As in several similar instances, alkaptonuria could be excluded as a cause of the pigmentation of the cartilages of the ears and sclerae. The method of production of the pigment remains obscure. It appears certain that ochronosis may be the result of either alkaptonuria or chronic carbolic acid poisoning.

2. In four cases of absolute irregularity of the heart, associated with fibrillation of the auricle, Lewis has observed at times the occurrence of bigeminy; in which the smaller beat regularly appeared at a constant interval after the larger, while the interval after the smaller beats was not regular. From the appearance of the electro-cardiograms, he concludes that the smaller beat was of ventricular origin.

4. This article is an extensive critical review of recent English work on the heart in connection with the use of the polygraph, and is not suitable for abstraction.

5. Hertz reviews the recent work on the motor functions of the stomach, especially with regard to the use of the x-ray, in which he has had a large personal experience.

6. As a result of the study of a large series of acute and chronic infections and anemias, Meek concludes that any lymph node is potentially a "hemolymph gland," i. e., may show blood instead of lymph in the sinuses. He found "hemolymph" nodes very frequently in the above conditions, and considers that there is no good reason for putting these structures in a separate category from the ordinary lymph nodes. Nucleated red cells in large numbers were found in hemolymph nodes in 3 cases, viz., pernicious anemia, sarcomatosis, and acute lymphatic leukemia: in the first there was a striking resemblance to the structure of the bone marrow. These findings render it probable that in rare instances red cells may be formed in the lymph nodes. With regard to the histological picture of the lymph nodes, degeneration of the germ centers was almost always met with, and very frequently proliferation of the endothelial cells. These latter were very often phagocytic, especially for red cells. Polynuclear leucocytes and rare myelocytes were sometimes present, and in two cases (sepsis and diphtheria) eosinophiles in large numbers. The writer's conclusion that the lymph nodes may serve as sites of formation for most of the varieties of leucocytes found in the blood is open to some question, as it is possible that the leucocytes, with the exception of the lymphocytes, were deposited in the nodes from the blood stream, as is known to occur, for example, in the case of eosinophiles in cancerous growths. [W. T.]

2. The method introduced by Uhlenhuth for the detection of tubercle bacilli consists in dissolving out the other substances of a sputum with antiformin, to which the tubercle bacilli are resistant. Hoffmann has applied this method to the detection of tubercle bacilli in tissues such as glands, etc., from animals, and thinks it of great value. He describes his technic.

4. v. Zebrowski has noticed that the glands in the axillary line are apt to be enlarged chiefly in the fourth and fifth interspaces in cases with pulmonary tuberculosis. Although he has only found this condition in about 20% of the cases, he has only found it in 2.58% of other diseases. The enlargement is usually on the side with the tuberculosis.

7. Klingmüller reports a few cases showing that the gonococcus can frequently cause direct warty growths of tissue. These are especially frequent around the anus in rectal gonorrhea in women. [C. F., Jr.]

1. In summarizing, the writer states the following views: That cases of chlorosis are not rare in which the blood is practically normal, but that these cases are as much helped by iron as are those having anemia; that anemia is not essential, but merely one symptom among others; that disturbances of menstruation, venous hum, retention of urine, and most of the subjective symptoms are not dependent upon anemia; that it is unlikely, inasmuch as iron is useless in most other forms of anemia, that the iron exercises a special influence on the formation of hemoglobin: and that the effect of the iron is to be sought in the underlying cause of chlorosis which is still unknown. He mentions the hypotheses of others that the internal secretions of the ovary or perhaps that of other glands may be at fault.

4. By studying the passage of food through the intestines by means of the x-ray, the writer discovered that when senna enters the cecum the colon empties itself rapidly.

18. Werner and Caan report the results of treatment of 255 cases of malignant tumor by means of Röntgen-rays. Their final conclusions are that this treatment should be used in connection with other methods, and that it is destined to fill an important place. It has a serious drawback in the fact that when the patient gets worse it is hard to know whether this is due to over or to under-dosage of the rays, and "apparently for some tumors there is no right dose." Generally, however, systematic and moderate dosage brings about relief of pain, limits the growth of the tumor, or improves the general condition and raises the spirits of the patient.

2. The author presents the reports from the hospitals in Amsterdam before and after the introduction of antitoxin in these institutions in 1894.

Of the severer cases of diphtheria, those requiring operative interference, the mortality has dropped from 55.2% to 26.8%. One hospital reports a mortality for all cases of diphtheria of 37.8% for the five years previous to the introduction of antitoxin, while the average mortality for the fourteen years since it has been in use is only 9.7%. 1. There is a theory that the excess of pepsin from the stomach is absorbed again in the gastro-intestinal tract and excreted by the kidney as urinary pepsin. In cases where the stomach pepsin is much diminished or absent, and the urinary pepsin high, the supposition is that cancer is present. In uncomplicated achylia no such relation exists. Such were the findings of these authors, although on a limited number of cases.

5. Contrary to the belief of some, Fischer finds that during wasting diseases old and apparently healed tubercular processes are apt to flare up. This flaring up consists of a not very severe activity of the process around the old site or extension, with not very virulent bacilli, into other organs or lymph nodes. These patients rarely die of the tuberculosis.

6. Askanazy gives a very excellent histological description of the vessel changes in the brain and meninges which occur during tuberculous meningitis and shows clearly their relation to hemorrhagic softening of the brain.

7. Kämmerer, reporting 4 cases of smallpox in which he studied the blood picture carefully, decides that there is a leucocytosis during the vesicular stage of smallpox of from 10,000 to 20,000. This disappears very slowly as convalescence supervenes. Upon a differential study he finds the lymphocytes are actually and proportionally increased and large lymphocytes are common early. The other cellular elements remain about as usual except that the polynuclear leucocytes are apt to be diminished.

9. Plesch carefully describes a new apparatus and the method of working it, by which he learns the functional capacity of the hemoglobin. [C. F., Jr.]

Correspondence.

LONDON AND ITS HOSPITALS.

[*From Our Foreign Correspondent.*]

London, July 28, 1910.

Mr. Editor: Voici le centre du monde! one surely feels inclined to exclaim on entering this great, grey, ancient metropolis, the symbol and incarnation of a world-wide dominion. Nor would such an expression be far amiss. Other cities are doubtless more magnificent than London. Paris dazzles one with the white and gold of its imperial splendor; New York stuns with its sheer economic and architectural mass; Edinburgh captivates with its romantic beauty: but London dominates with its immense and immemorial significance. Not only is it inconceivably vast — nearly twenty miles long now, — the only city beyond whose confines one cannot see from a high vantage-point at the center; not only does it present the sign and evidence of colossal wealth and vested power; but it represents, — from the tower that still stands guard at the east to the hoary pile of the parliament buildings that crown the waters of the river at Westminster, — the center and hearth-stone of all the heritage and tradition of our great English-speaking race, whose children turn back from every quarter of the globe to

"The hush of the Abbey that makes us We."

If England be still

"Model to her inward greatness,
Like little body with a mighty heart,"

London is surely that heart, and "out of the heart are the issues of life." Indeed, it is this humanly and racially representative character which makes London great in spite of its size, which saves it from becoming a mere sordid bulk, which makes it, for one New Englander at least, the most homelike city in Old England.

There is so much to see and to do in London that one might spend a lifetime here and know as little of it as we easterners in America do of the great west of our own country. London has boroughs by the dozen, churches and theatres by the score, hospitals and railroad stations by the hundred, streets and houses by the thousand, and inhabitants by the million. In its profusion one can only gather a bit here and there, see something, ponder much and remain in reverent stupefaction at the last.

Our first medical experience in London was a visit to one of its old hospitals, recently rehoused in new and splendid buildings in connecton with the University College Medical School. The intimacy of relation between school and hospital is as noteworthy here as in Ireland, an ideal towards which we in America are working but as yet have by no means fully attained. Five years of medical study are required in all the London schools, of which the first two are spent in laboratory, the remainder in clinical work. Following this, ambitious men who can afford it take a

further service as residents, corresponding to our house-officers, in the hospitals, for terms varying from six months to two years. In London these positions are unpaid, but in many of the county hospitals, as we learned, small salaries are offered to attract good men. The complaint of young doctors is everywhere the same: "Practise is rotten and living is high." "A fellow can't afford to marry here, don't you know," said one London surgeon, not so young or unsuccessful a man either.

Other hospitals that we visited in London showed much that was interesting, little that was startlingly novel. A striking thing in all was the importance attached and the attention paid to pathology. Restrictions on autopsies are not nearly so stringent as with us, and a full *post-mortem* examination is made as a routine on every case dying in hospitals, unless objection is lodged by the patient's relatives within a few hours after his death. The obtainment of written and witnessed consent is unnecessary, and never troubles the souls of pathologists or superintendents. Moreover, governing boards show an intelligent appreciation of the value of pathologic research, and appropriate liberal funds for the equipment and maintenance of laboratories. The result is not only that there is a large amount of pathologic material but that extensive use is made of it, and every hospital of any size has a museum of considerable extent and value.

Clinically, English methods and technic do not differ widely from our own. London obstetrics as we saw it at the large lying-in hospitals, is even more like our own than that of Dublin. In the treatment of contracted pelvis, pubiotomy, so much in favor at present at the Rotunda and on the continent, is disapproved by the majority of London obstetricians, who seem to be divided into two camps, one preferring Cæsarian section, the other induction of labor at the thirty-fifth week for all cases on the borderline of possibility. Surgery differs little from that in our own country. There seems to be a widespread distrust of catgut for fear of tetanus and other infections, so that silk is much more extensively used than is now the custom with us. Moreover, simple boiling is not considered sufficient for its sterilization, but it is also steeped many hours in carbolic acid and used impregnated from a carbolic solution.

The great medical event of our stay in London has been the annual meeting of the British Medical Association, held in the buildings of the Imperial Institute at Kensington. To visit this immense pile, of great architectural beauty and magnificence and covering many blocks with its allied museums and schools, is in itself a bewildering and impressive revelation. And the special exhibitions, of specimens, instruments, books, drugs, foods, electrical apparatus and appliances of all sorts, arrayed there for this occasion, were enough to have occupied many hours with pleasure and profit. Where life is too rich one sometimes gets less out of it than when its possibilities are limited and its issues more clearly defined.

Apart from the general and representative meetings of the association, there were twenty-one sections, covering the whole field of scientific and practical medicine, among which it was almost as hopeless to choose as among the riches of Midas. The JOURNAL will of course have a full official account of the proceedings, which must relieve your correspondent of the duty of reporting them. Decidedly the most interesting of the few sessions we could attend was that of the section in surgery, under the presidency of Sir Victor Horseley, which considered the operative treatment of simple fractures. The discussion was opened by Mr. Arbuthnot Lane, who advocated, as he has done for some years, early, fearless operation, under the most rigorous asepsis, on cases of simple fracture in which perfect reposition of the fragments, as tested by the x-ray, cannot be readily obtained by the usual manipulative measures and maintained by splints. He believes that our standards of satisfactory anatomic and functional result should be much higher than they are, and that our functional results after fracture will become perfect only when anatomic results are perfect. In all cases, after incision and correction of displacement, he secures fragments in position by means of steel plates and screws, which are left to heal permanently in place, except in epiphyseal separations, when they are subsequently removed for fear of interference with growth. Wire he has abandoned, as not affording sufficiently secure fixation. Mr. Lane showed a large series of beautiful x-ray plates, which were an admirable illustration of his results and strong argument in favor of his method, as were also his cases to be seen at Guy's Hospital and Great Ormond Street. There was much further discussion, in which men of eminence in England and from the continent took part, and although some opposed Mr. Lane's contention in whole or in part, the majority favored his conclusion, though recommending great discretion in the selection of cases and, as some one happily added, of the operator.

Apart from medical meetings, visits to hospitals, and operating clinics, which have claimed most of our time, there have been few objects of special interest. We have read some headlines about the terrific heat-wave in the States, while we were shivering in the rain with the thermometer at 50°, and about the Crippen murder, whose horrid details have doubtless been served up with the usual disgusting minuteness in America. It is gratifying to find that "Dr." Crippen is not here considered in any sense a representative of the American profession.

Just at present there is some excitement over a recent outbreak of foot-and-mouth disease near Ripon in Yorkshire. Parliament, already distracted by the suffragettes (of whom, by the way, we have seen and heard not a few), by the income tax, by free trade and protection, and by the oath of accession, has had to turn its attention to this episode also, and has ordered a large number of cattle in the infected region killed, and others isolated to prevent extension. The department of agriculture of Ireland has also forbidden the importation of cattle and sheep from Great Britain into Ireland. Twenty-seven years ago, when the disease first broke out in England, thousands of cattle died of it or were killed in the effort to stamp it out, and the loss and expense of this epizoötic were estimated at over $12,000,000. There have been since two small outbreaks, one in Kent in 1902, and one in Edinburgh in 1908, both of relatively slight extent and destructiveness. It is hoped that the rigorous measures now adopted will soon check the present eruption of the disease. A new form of parasitic mange has also been reported among horses in East Suffolk, and steps are being taken to prevent its further spread.

But though there are parasites a plenty for man and beast, the vegetation of these blessed islands seems entirely free from them. There are no gipsy moths, brown-tails, leopard-moths, elm-leaf beetles, army worms, or any of the thousand and one scourges that afflict our trees like the hosts of the Philistines. Here everything flourishes like the green bay of Scripture, even in the city, from the great elms to the ubiquitous ivy and the grass and flowers that sprout without visible sustenance from roofs and wall-tops. The flora imbibes moisture perpetually from the continuously oozing atmosphere, and grows so vigorous in consequence that no worm can afflict it. For the same atmospheric reason there is no dust in the streets, and singularly enough there are no mosquitoes. We have seen only three house-flies since landing.

In connection with the meeting of the British Medical Association, there has been a curious resurrection of that apparently unlayable medical ghost, the question whether or no Napoleon died really of cancer of the stomach. Whether the fact were pathologically proved or not, it might seem sufficient that the great Corsican has been satisfactorily dead for nearly eighty years, and that even his memory has ceased to trouble the peace of Europe. But someone has recently unearthed in the Museum of the Royal College of Surgeons two specimens purporting to be secondary carcinomatous growths from the emperor's intestine. Microsopic examination of these, however, now shows them to present merely "enlarged lymph follicles, containing extravasated blood," and upon this discovery is based the surprising contention that Napoleon did not die of cancer. Aside from question as to the value or interpretation of this evidence, there seems as little profit in further discussion of the matter as in the query whether Cæsar and St. Paul were epileptics or Joan of Arc a paranoiac. Peace to their dust. We shall all soon be as dead as they, and in spite of their afflictions they managed to become a deal more famous than most of us will ever be, who make question about them.

After all, the greatness of London, in retrospect, seems

to consist less in what it is than in what it represents. In itself, the city is

"All valiant dust that builds on dust,"

but that dust is the dust of Nelson and Wellington and Cromwell and Gladstone and hundreds of their mighty peers. And out of that dust goes forth an inspiration of power to those who derive the English blood and speak the English tongue, from Labrador to Australia, from Gibraltar to the Golden Gate.

MEDICUS PEREGRINUS.

DEATHS UNDER ANESTHETICS.

CITY CORONER'S OFFICE AND COURT,
LONDON, E. C., ENGLAND,
Aug. 5, 1910.

Mr. Editor: An inquest was held by the city coroner in his Southwark Court on Friday last the 29th of July, 1910, relative to the death of Wm. Jno. Faulkner, aged thirty-one, a tramcar driver, of Thorburn Square, Bermondsey, who died in Guy's hospital under ether, given for the purposes of an operation. The coroner, Dr. Waldo, on opening the case, told the jury that the house-surgeon who gave the anesthetic had written to him and offered to certify the cause of death as a natural one from peritonitis. He (the coroner), however, was obliged under the provisions of the Coroner's Act to hold public inquiries on all cases reported to him when there was a reasonable presumption that the death was a violent or unnatural one; and in all such cases it was his custom to order an autopsy to be made by an independent skilled pathologist.

The widow stated that on the 2nd instant her husband who was a strong, healthy and sober man, after partaking of fried fish and chips the previous day, had complained of pain in his stomach. A local doctor, who was called in, sent him to Guy's hospital where he arrived the same day at 4 P.M. Not being satisfied with the stated cause of death she had asked the coroner to hold an inquest. Mr. Claud H. Mills, house-surgeon at Guy's Hospital said the case was one for immediate operation, and witness gave ether by the "open method." Five minutes later the patient died suddenly, the abdomen having been shaved preparatory to a section of the abdomen for appendicitis which operation had not been commenced. Prior to giving the ether (made from rectified spirit and not from dutiable ethylic alcohol) he had injected strychnine. Without an operation the deceased had only "a 1% chance." Asked by the coroner why the giving of the anesthetic had not been undertaken by one of the ten visiting special anesthetists at Guy's Hospital considering the fact that the patient was suffering from frequent vomiting and the seriousness of the case, the doctor said the patient was prepared for the operation at 6 P.M., by which time all the specialists had left the hospital.

Before entering office as house surgeon, witness had produced satisfactory evidence of knowledge in the administration of anesthetics which he had given on 380 occasions without any previous fatality. Mr. Ernest C. Hughes, acting resident surgeon at Guy's Hospital, said he did not think the case required any very special skill and the previous witness was a highly competent anesthetist. The visiting anesthetists at Guy's Hospital were looked upon more as teachers than as actual administrators of anesthetics.

The coroner remarked that with regard to Guy's hospital he noticed that in nearly every one of the 44 cases of those reported as having died under anesthetics during the past nine years — on all of which he had held public inquests — the anesthetic had been given by junior residents. In another great general hospital during the same period where it was the custom for the anesthetic in serious cases to be given by visiting and resident specialists there had been fewer fatalities, and very few indeed, not more than two or three in number at the hands of the junior residents.

In difficult cases he could not help feeling that it would be better if anesthetics were administered either by seniors or if by juniors at least in the presence and under the guidance of specialists. In October, 1907, a Southwark jury inquiring into the death of a young married woman, (Mrs. Morgan) who died under chloroform given by a junior resident for an operation for the cure of exophthalmic goiter, recommended this reform to the authorities at Guy's hospital, also that in future full details of all administrations of anesthetics should be kept in proper registers by the hospital authority. In reply Mr. Hughes said that the jurors' rider in question had resulted in a full inquiry by the hospital authority. As a practical outcome of such inquiry the four following reforms had since been introduced:

(1) The appointment of two additional teaching visiting special anesthetists, now making ten in all at the hospital.

(2) The requirements that all candidates should, before appointment on the junior staff, produce evidence of special practical knowledge in the administration of anesthetics.

(3) The keeping of a full register of all administrations of anesthetics.

(4) The introduction of the administration of ether by the "open" method, such as was in use on its first discovery and at the present time largely practised in the United States of America.

Dr. Bernard Spilsbury, lecturer and pathologist at St. Mary's Hospital, who had made an autopsy in the presence of Mr. Mills, the anesthetist, said death was due, in his opinion, to the rupture of a small ulcer in the intestine which had led to peritonitis. This had caused vomited matter to regurgitate and lodge in the air-passages whilst the patient was under the influence of the anesthetic, thus producing suffocation. He did not think death had been hastened by the ether. In any case the patient would probably have died within a short time as a result of the peritonitis. He could not say whether or not the fried fish and potatoes or other food taken by the deceased had any connection with the fatal result. In answer to the coroner, the witness said they had a resident special anesthetist at St. Mary's Hospital which was the case also at a few of the other big metropolitan hospitals.

The surgeons agreed with Dr. Spilsbury as to the cause of death.

In summing up, the coroner said he felt sure all would be pleased to hear of the reforms introduced and of the decrease of late in the number of deaths under anesthetics at Guy's Hospital. Sonce 1907 in which year there were 11 fatalities the deaths reported were few and far between. Two deaths had been inquired into during the present year. In the first of these — a death under ether given by the "open" method — the verdict was to the effect that the cause of death was not in any way influenced by the anesthetic. The second case, the one now under consideration, seemed on the evidence to be a similar one to the former death. As a result of inquests referred to, questions had from time to time been asked in the House of Commons. This had led to the late Home Secretary (Mr. Gladstone) referring the matter to the Departmental Committee appointed to inquire into the law relating to coroners and the practise in coroner's courts. The first recommendation of this committee in their report was to the effect that "Every death under an anesthetic should be reported to the coroner, who, after inquiry, should determine whether it is desirable to hold an inquest or not."

With the first part of this suggestion he heartily agreed, since it was a well-known fact that only a small proportion of deaths under anesthesia in private practise including nursing homes ever came to the notice of registrars or of coroners. With the latter part of the recommendations, however, he disagreed — since he did not think such a change in the law at all favorable to the public interest. He preferred the English open method of inquest by coroner and jury to the private inquiry as held by the procurator-fiscal in Scotland into violent or unnatural deaths. Such secret investigations were, he thought, hardly favorable to a full statement of the facts with regard to so delicate a matter as that of fatal anesthesia.

The jury returned a verdict in accordance with Dr. Spilsbury's evidence.

F. J. WALDO, M.A., M.D.,
H. M., Coroner for the city of London and Southwark.

RECORD OF MORTALITY

LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND OTHER OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED AUG. 3, 1910.

BANKS, C. E., surgeon. Granted seven days' leave of absence from Aug. 1, 1910.

WERTENBAKER, W. P., surgeon. Directed to proceed to Richmond, Va., upon special temporary duty. Aug. 2, 1910.

FOX, CARROLL, passed assistant surgeon (on leave). Directed to report at the Bureau upon special temporary duty. Aug. 1, 1910.

KORN, W. A., passed assistant surgeon. Directed to proceed to Point Pleasant, N. J., for the purpose of making examination of keepers and surfmen of the Life-Saving Service. July 30, 1910.

SWEET, ERNEST A., passed assistant surgeon. Granted four days' leave of absence from July 21, 1910, under paragraph 191, Service Regulations.

SPRATT, R. D., passed assistant surgeon. Granted five days, leave of absence from July 23, 1910, on account of sickness.

FROST, W. H., passed assistant surgeon. Directed to proceed to Des Moines, Iowa, upon special temporary duty. July 25, 1910.

MULLAN, E. H., passed assistant surgeon. Granted two days' leave of absence from July 30, 1910, under paragraph 191, Service Regulations.

PREBLE, PAUL, assistant surgeon. Granted one month's leave of absence from Aug. 8, 1910.

KEARNY, RICHARD A., assistant surgeon. Directed to proceed to San Francisco, Cal., and report to the medical officer in command for duty and assignment to quarters. July 21, 1910. Directed to report to the medical officer in command at Chicago, Ill., for temporary duty en route to station. July 25, 1910.

DRAPER, WARREN F., assistant surgeon. Directed to proceed to Angel Island, Cal., and report to the medical officer in command for duty and assignment to quarters. July 21, 1910.

GILLESPIE, JULIAN M., assistant surgeon. Directed to proceed to Honolulu, Hawaii, and report to the chief quarantine officer for duty. July 25, 1910. In addition to present duties, directed to report to commanding officer Revenue Cutter "Thetis" from time to time for temporary duty. Aug. 3, 1910.

STILES, CH. W., professor. Detailed to represent the Service at the meeting of the International Zoological Congress at Gratz, Austria, Aug. 15-20, 1910. July 27, 1910.

BLANCHARD, J. F., acting assistant surgeon. Granted three days' leave of absence from July 11, 1910.

CLEAVES, F. H., acting assistant surgeon. Granted three days' leave of absence from July 28, 1910, under paragraph 210, Service Regulations.

DELO, J. M., acting assistant surgeon. Granted seven days' leave of absence from July 16, 1910, under paragraph 210, Service Regulations. Granted seven days' leave of absence from July 24, 1910.

DUFFY, FRANCIS, acting assistant surgeon. Granted six days' leave of absence from Aug. 3, 1910.

HARKIN, F. MCD., acting assistant surgeon. Granted fourteen days' leave of absence from Aug. 1, 1910.

HAMILTON, H. J., acting assistant surgeon. Leave of absence for four days from July 19, 1910, amended to read four days from July 26, 1910.

ONUF, B., acting assistant surgeon. Granted seven days' leave of absence from July 22, 1910, under paragraph 210, Service Regulations.

SCOTT, J. T., acting assistant surgeon. Granted twenty-four days' leave of absence from June 3, 1910.

STEVENSON, J. W., acting assistant surgeon. Granted thirty days' leave of absence from Aug. 3, 1910.

MACDOWELL, W. F., pharmacist. Granted twenty-eight days' leave of absence from Aug. 10, 1910.

MAGUIRE, E. S., pharmacist. Granted thirty days' leave of absence from Aug. 6, 1910.

RYDER, L. W., pharmacist. Granted one day's leave of absence July 25, 1910, under paragraph 210, Service Regulations.

STIER, C., pharmacist. Granted one day's leave of absence July 8, 1910, under paragraph 210, Service Regulations.

BIERMAN, C. H., pharmacist. Granted fourteen days' leave of absence from July 26, 1910. Leave of absence for ten days en route to station amended to read nine days en route to station.

CANNON, CLAUDE C., pharmacist. Directed to proceed to Vineyard Haven, Mass., and report to the medical officer in command for duty and assignment to quarters. Aug. 2, 1910.

RECENT DEATHS.

DR. SEYMOUR J. NOLLEY, an old practitioner of Brooklyn, N. Y., died on Aug. 9. He was born in Dorset, Vt., and served as a surgeon in the Army during the Civil War. For twelve years he was a medical inspector in the Brooklyn Health Department.

DR. WILLIAM HENRY HULL has recently died in Essex, Mass., at the age of seventy-eight. He was born in Groveland. Received his early education in Georgetown, and later in Dartmouth Medical School. During the Civil War he served as surgeon to two Massachusetts regiments, and at its conclusion took a degree in medicine from the Harvard Medical School. After twenty-two years of practise in Essex, he settled in East Boston where he remained in active practise for nearly thirty years, with certain intermissions.

DR. JOHN BRUIN RICH, a retired New York dentist, died on Aug. 12, in his one hundredth year. He was a native of New York City, and was educated at the military academy of St. Cyr, France. Later he studied dentistry, and began practising in New York in 1833. He was one of the founders of the American Dental Association, and among the organizations of which he was president were the American Microscopical Society, the Bailey Microscopical Society, the Physical Culture Club, and the Hundred Years Club. He was remarkable for his physical powers, and it is stated that as early as 1830 he had the reputation of being the strongest man in the world.

A REPORT OF THE SCOLIOSIS DEPARTMENT OF THE CHILDREN'S HOSPITAL, BOSTON.

BY JAMES WARREN SEVER, M.D., BOSTON,

Junior Assistant Surgeon, Children's Hospital; Member American Orthopedic Association.

INTRODUCTION.

For the past sixteen years there has been special provision made for the treatment of scoliosis in the Out-Patient Department of the Children's Hospital, that is, a special room has been set apart for use as a gymnasium, and such essential apparatus as was needed has been supplied. It was found necessary to run the department as a separate clinic, not only on account of the special character of the work, and the large attendance, but also on account of the necessarily frequent and careful individual attention of each case.

AIMS.

The scoliosis clinic has been conducted so that any child, boy or girl, applying there for treatment, and a suitable hospital case, may be received. The supply of patients is beyond our capacity, however, so that we always have a large waiting list to draw from as needed. We propose to conduct the clinic so that each child may have frequent individual attention, exercises and such apparatus as braces or jackets which may be essential to its progress.

ATTENDANCE.

We insist on regular attendance at the clinic after admission, and each case is given a card which states that, if there are two successive absences without a satisfactory written excuse, they will be dismissed from the department; also that patients who are tardy to their appointments six times during the year without written excuses will be dismissed. Each absence or tardiness must be explained.

It is necessary to be strict in these rules, for otherwise we cannot get results. To get results, both patients and attendants must be on hand promptly and mean business. Any department conducted on any other lines is most unsatisfactory.

From the middle of June to the first of August the clinic is run at a much reduced size by volunteer assistants, and from August first to the last of September is closed, for it has been found by experience that it is not well to work children already delibitated through the hot weather. In proper apparatus, that is, jackets or braces, they lose nothing by this short period of rest.

The clinic is open for three days a week from 2 to 5 P.M., and one morning from 10 to 1 P.M. Difficulties in administration have so far prevented us from making it a daily clinic.

CONDUCT OF CLINIC.

The clinic is under the direction of the senior out-patient surgeon, and he is assisted by one of the junior assistant surgeons, who does the actual work of the clinic and sees all of the cases at regular intervals of not more than two weeks. All new cases are seen by him and put on the waiting list, if there is no room for them in the clinic. When formally entered, they have photographs taken, are x-rayed and such measurements as are necessary are taken. All old cases have measurements and photographs taken at definite intervals, usually about one month apart. One day a week is usually devoted to the application and fitting of plaster jackets.

Photographs are taken under fixed conditions. The patient stands at a distance of seventy inches from the camera, and all pictures are taken by daylight after experimenting for a year with an arc light, which was not found to give satisfactory pictures owing to too great lack of contrast.

ASSISTANTS.

One of the greatest difficulties we have to meet in the conduct of a successful clinic is that of efficient assistants, i. e., properly trained persons who give and conduct the gymnastic exercises. Formerly the gymnastic work of the clinic was given by volunteer assistants, eight to ten in number, under the charge of a graduate of one of the normal schools of gymnastics. These assistants were usually graduates or advanced students, who served three months at a time and who had no previous theoretical or practical training in corrective gymnastic work. This arrangement was not satisfactory, for they were under no control as to discipline, attendance or conduct. Their work was on a most informal basis, and they received but scant instruction in scoliosis.

The difficulties under this plan were as follows:

(*a*) Lack of regular attendance on the part of both assistants and patients.

(*b*) Lack of punctuality.

(*c*) Inadequate knowledge of the treatment of scoliosis.

(*d*) Impossibility of discipline over volunteer workers.

The lack of efficiency resulting fron these conditions represented poor administration and a consequent lack of results in the treatment of scoliosis.

This question of proper assistants can best be solved, I believe, by an alliance with some educational institution which will provide regular assistants, who come to the clinic as a part of their school work, and who are, therefore, under discipline as to attendance and conduct. Some years ago we made such an alliance with the Boston Normal School of Gymnastics (now affiliated with Wellesley College) by means of which students were sent to the clinic to give the necessary exercises to the cases, in return for which they were to receive clinical instruction in scoliosis from some of the members of the staff. These students receive a lecture on scoliosis once in two weeks from the senior out-patient surgeon, with a demonstration of cases and an analysis of the different types of scoliosis. These lectures last through the school year.

Two methods have been tried in regard to the work and attendance of the students. At first they came for periods of a week at four intervals during the year. This proved most unsatisfactory on account of the following reasons:

(*a*) Frequent change in patients.

(*b*) Loss on continuity in the treatment of any given case, and consequent lack of interest.

(*c*) Too long periods between instruction and opportunities to apply their knowledge.

The plan was changed for the following one:

(*a*) The students to come daily for two months at a time.

(*b*) Each student to have her own case and to follow the case and to assist in the treatment of it in every particular.

(*c*) To have daily instruction in the practice and theory of scoliosis besides the lectures.

and record of each case besides a practical knowledge of the corrective treatment.

These students have been under the charge of a teacher from the school, who also acts as administrative officer of the clinic generally, and it has been clearly understood and faithfully carried out that the direction of the treatment was to lie wholly in the hands of the staff. This question has never offered the slightest difficulty. The presence of these students has been of great help to the clinic in enabling us to treat more cases than we otherwise could and in giving us most satisfactory assistants. Their presence has been a great incentive to keeping up a high standard of efficiency. Owing to the various administrative difficulties which developed following the affiliation of the Boston Normal School of Gymnastics with Wellesley College, our connection with that

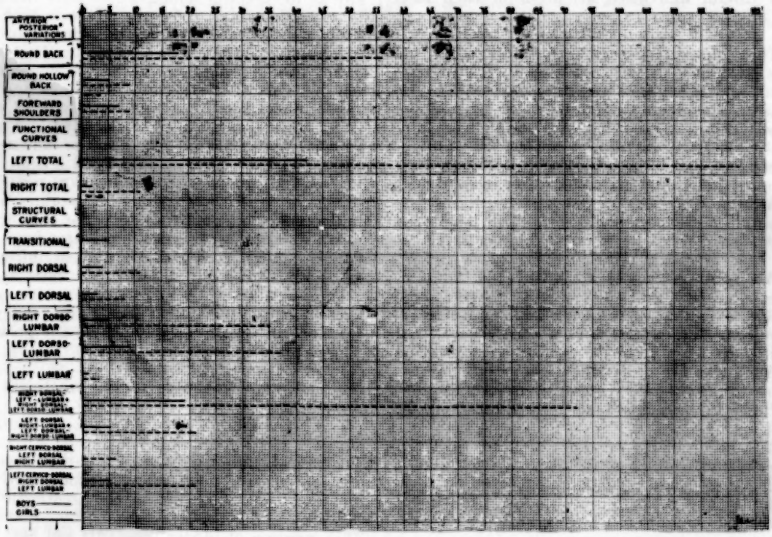

Chart I shows totals of boys and girls in each class.
(Figures at top show number of cases.)

This plan has been found much superior to plan one, better results are obtained and more interest shown. A number of the students who have desired post-graduate work are retained to act as assistants to the administrative affairs of the clinic.

It is the purpose of this clinic, first, to improve our cases, and, second, to teach our students to recognize simple and compound cases of scoliosis, to become familiar with measuring and keeping adequate records of cases, to assist in photographing and in the application of jackets and braces. In other words, they are given a definite analysis and routine to follow in the examination

institution had to be severed, and the department is now ably looked after by a paid administrative officer, a graduate of the Boston Normal School of Gymnastics, who has under her charge and instruction the senior class of Dr. Dudley Sargent's School of Physical Education.

Records of Cases.

All cases are recorded in a routine manner on a suitable record card. The order of examination I will outline to give an idea of our routine and also for the reason that it may be of help to others who may wish to establish a similar plan. It is not perfect, but is sufficient, gives one an ade-

quate picture of the case and usually establishes a diagnosis and, therefore, suggests the treatment.

General conditions: Development. Height and weight as compared to age.
Nutrition.
Deviation in frontal plane.
Girth of chest { Expanded. / Contracted.
Displacement of trunk.
Curve of spine.
Length of legs { Standing. / Lying.
Height of shoulders.
Deviation in horizontal plane.
Feet { Weak. / Pronated.
Rotation of shoulder girdle.
Rotation of thorax.
Rotation of lumbar vertebræ.
Heart { Sounds. / Area.
Lungs.
Deviation in sagittal plane.
Physiological curves.
Forward shoulders.
Pelvis. Abdomen.
Head. Position.
Flexibility:
Forwards.
Sideways.
Power of correction.
Diagnosis.

HISTORY OF CASE.

In taking the history of the case the following points are noted:

Obstetrical history.
Infancy, teething, feeding, walking.
Vital resistance:
Liability to fatigue or colds.
Children's diseases, injuries, hereditary diseases.
Mentality: Grade in school, home study.
Deformity: Heredity, appearance, development, treatment.
Personal hygiene:
Daily routine; clothing, how worn; appetite.
Conditions of sleep.
Conditions of eyes, ears, nose and throat.
Occupation, outdoor activity.

CLASSIFICATION OF CASES.

There is no arbitrary division of the cases made so far as the treatment is concerned, but they rather tend to group themselves into three large classes, which will be described and their treatment outlined in a general way as follows:

CLASS I.

Faulty attitude, including round shoulders, forward shoulders, round, hollow back and functional scoliosis are treated by gymnastic exercises four times a week, and as they improve the frequency of the attendance is diminished. Some cases of round or forward shoulders are so resistant that exercises have no appreciable effect on their condition, and they are put into a plaster jacket with the idea of holding them in the correct upright position and at the same time affording an opportunity for padding the jacket in front so as to stretch gradually the constrictions about the shoulders. These jackets are very high in front of the shoulders and come up behind so as to fix the lower portions of the scapulæ. They are worn for six to twelve weeks, and their removal is followed by a continuance of their gymnastic work. They usually prove most efficient and result in marked improvement.

Functional scoliosis is usually successfully treated by exercises alone, and jackets or braces are not required, except in a few cases. Slight structural scoliosis is treated in the same way, and, if satisfactory improvement does not occur, by jackets.

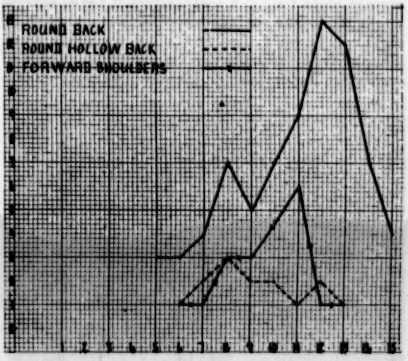

Chart II shows relation of antero-posterior variations. (Figures at side show number of cases; figures at bottom give ages by years.)

CLASS II.

Structural scoliosis of more than slight grade is best treated by jackets, either with or without exercises. In the moderate structural scoliosis the cases are best treated by removable jackets, which are worn all the time, except during the gymnastic work. These jackets are made from remodeled plaster torsos, which have been made from a jacket taken of the patient in the prone position, or standing with head extension, depending on which one gives the best corrected position. These torsos are further corrected by shaving off over the rotation and adding on the concavities. They may be made still more efficient by cutting them in two and setting the halves apart, the distance being determined by the patient's flexibility.

A check is kept of the efficiency of these jackets by means of frequent measurements of height. Four measurements are recorded as follows:

Best standing position.

Position with hands on hips, pushing up (limit of flexibility).

Position held by jacket.

Position with hands on hips pushing up in jacket.

If a case is held at her limit of flexibility in the jacket, as shown by comparing her height record when pushing up with hands on hips, with her height when in jacket, that is all one can expect to do at that time. As her flexibility increases

through exercises and use of the jacket, then the extra flexibility must be taken up by pads, and later by a new jacket, following a remodeling of the plaster torso. In general it may be stated that from three to six weeks is about as long as a jacket is really efficient, and it becomes necessary to alter the torso, or to take a new cast.

Jackets must be worn for long periods, that is, several years, to obtain permanent results. It is better to have these jackets made of plaster, for they are cheaper and do not take long to make, and are not worn long. A leather jacket takes several weeks to make, is expensive and in a growing child will probably not fit for any length of time. This is true only during the growing stages of scoliosis. Later leather jackets are satisfactory.

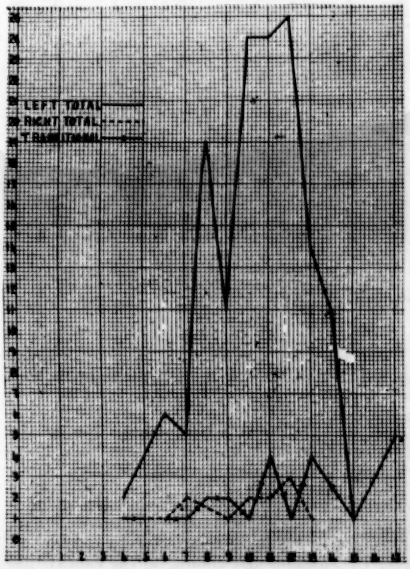

CHART III shows relation of physiological curves. (Figures at side show number of cases; figures at bottom give ages by years.)

The exercises in these moderate cases are for two purposes, namely, flexibility first and then muscular development. Jackets may be made more corrective and efficient by cutting out the greater part of the concave side and allowing the patient to expand through this opening, and also in mid-dorsal and upper-dorsal cases by fastening a steel shoulder pad on the jacket in front of the high shoulder to act as a point of counterpressure to that shoulder and prevent its falling forward.

LEATHER JACKETS.

There are two kinds of leather jackets in common use at the clinic. One is made of rather heavy leather, fitted wet over the corrected plaster torso, and when dry is saturated with a solution of barbary wax. This soon dries and makes a very hard and durable jacket. For purposes of reinforcement light strips of steel may be riveted on the outside at the areas of greatest strain. These require about ten days to two weeks to make.

The other type is the so-called leather celluloid jacket, made of light weight leather, fitted to the torso as before and lined with several layers of celluloid dissolved in acetone, which is painted over several layers of gauze on the inside of the jacket. These jackets are more efficient when fitted with steel strips as reinforcements, and are lighter than those made of barbary wax. Both types are perforated for the sake of coolness and ventilation.

Whereas the exercises in the first class of cases are usually symmetrical and carried out in the self-corrected position, except, of course, the passive stretching exercises for the round shoulder cases, the exercises for Class II are always those of special selection and asymmetrical in character, such as those which increase the backward flexibility of the spine against the direction of the deformity and increase the rotation of the thorax in the direction of the normal plane. In addition to the usual apparatus for increasing flexibility, we have been using also the symmetrical and asymmetrical creeping exercises as devised by Klapp. We have not been able to get the best results from these on account of our limited floor space. These latter exercises are an aid in increasing flexibility in some cases, but are by no means efficient alone to the exclusion of other treatment in obtaining results.

Exercises should not be pushed beyond the limit of fatigue, and the length of treatment, the period of exercises and the extent to which they may be pushed depend wholly on the vigor of the child.

CLASS III.

Cases which come into this class are those severe ones in which the curve has become more or less fixed, and in which there is very little hope of any cure. These cases have had periods when treatment might have been of use, but have passed that stage and arrived at a condition of severe structural deformity through neglect. They are usually the result of rickets or congenital deformities or deficiencies and infantile paralysis. About all one may hope to do is to hold the deformity at its present condition and to prevent increase. Some cases have been considerably improved by wearing permanent jackets put on in the corrected position without forcible correction. These jackets have large windows cut out of them through which the areas of rotation may be padded from time to time to decrease the deformity. They are worn for long periods of time, often a year, and in suitable cases cause marked improvement. These cases, then, may be considered as belonging to Class II, and their treatment is carried along under the plan outlined above.

APPARATUS AND EQUIPMENT.

In view of the small space at our disposal, we have done well by it, and I wish to describe in a general way some of the apparatus in use at the clinic. The essential apparatus is as follows.

1. Stretching board (two) (Lovett).
2. Sayer head sling and trapezes.
3. Adams' machine.
4. Lorenz rocker.
5. Roller.
6. Stretcher frame.
7. Pelvic machines.
8. Dumbbells, chest weights and wands.
9. Schultess' machine.

1. Stretching board (Lovett). Correction of the lateral curve of the spine is to be obtained most economically by pressure on the spine through the medium of the ribs and combined head traction, which is most easily secured by having the patient lie prone. The corrective force should be divided into two elements, — the force to correct the rotation and the force to correct the side deviation. This may be done by means of this board.

"The patient lies face downward, with knees flexed, on a board three feet wide by four feet long. Assuming the case to be one with a right dorsal curve, a broad canvas strap is passed around the left upper thorax, over and under the patient and fastened to a cleat on the right side of the board. This furnishes a point of pressure to the left against the upper thorax at the level of the axilla. A broad canvas strap is then passed around the pelvis of the patient, above and below, and is fastened to a cleat at the right side of the board. This furnishes a point of pressure to the left at the level of the pelvis. A broad canvas strap is then passed around the thorax at the level of the greatest point of the curve. It passes above and below the thorax, and its upper end is fastened to a cleat at the left side of the board. Its lower or under end is fastened by means of a cord into a compound pulley attached to a cleat at the left side of the board. By means of this pulley any reasonable degree of force may be exerted against the right side of the thorax, pulling it to the left, and at the same time that it pulls it tends to reduce the rotation from the fact that its upper end is fastened and its lower end moving towards the pulley." Head traction is applied in combination with this. Structural cases are treated with this apparatus from fifteen to twenty minutes daily. Dr. Lovett's board does not use head traction, but is an addition made by the writer.

2. The Sayer head sling is familiar to all and is used for passive stretching, as are also the trapezes.

3. Adams' machine. This is a machine devised by Dr. Z. B. Adams, of Boston, for doing the same thing as is done by the board devised by Dr. Lovett.

4. Lorenz rocker. This apparatus is designed for use in scoliosis and round back cases, and utilizes the body weight as a corrective force combined with forcible stretching. It consists of a heavy gas pipe stand furnished with an upper horizontal plane and a long, slanting plane covered with canvas, each about two feet wide, and pivoting on the gas-pipe standard at the junction of these two. At the junction point is a heavily padded leather roller. The lower frame or plane is provided with a counter balance to insure easier operation.

The patient lies reclining at about 45° to the floor, on his back, on the lower frame, and this is then lifted to a horizontal position. He then grasps in each hand a strap which is attached to the upper end of the horizontal or fixed frame, the part to be corrected resting on the leather roller. The inclined frame is then lowered sufficiently to create considerable pressure and stretching force over this area to be corrected. This is repeated several times and is used daily.

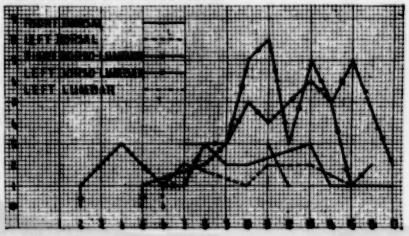

CHART IV shows relation of simple structural curves.
(Figures at side show number of cases; figures at bottom give ages by years.)

5. Roller. The roller is used in cases of round back and forward shoulders principally. It consists of an upright steel rod about eight feet long fastened to a square platform. It is hinged in the middle so as to enable it to be moved forward and backward. On the upper arm is a sliding saddle made of a half circle of steel, the ends of which are joined by a wide leather band. Above this is a sliding rod used as a lever, and above this is a handle bar for the patient to grasp. The patient stands on a stool and grasps the handle bar, and the saddle is adjusted opposite the deformity to be corrected and the lever is then grasped and the patient lifted off the stool. The hanging body weight is then in action as the corrective force. This procedure is repeated several times daily.

6. Stretcher. This apparatus is also used for the forcible correction of stiff, round back and shoulders and is described as follows:

"The apparatus consists of an oblong gas pipe frame of the ordinary pattern. Fastened to this near the middle, and hinged so as to be raised to any degree, is another section of gas pipe lying on the frame proper, and of the same shape and size as the upper half of the frame. To this movable section is fastened, at right angles to it, and movable on it, a gas pipe bridge rising about eighteen inches from the movable section. When prepared for use two strips of webbing, one over the other, run from each of the buckles

at the bottom of the frame. The lower two strips are tightly drawn and run to the buckles at the end of the movable section. The upper two are loosely fastened to the bridge over the movable section. The cross pieces are tightened, and the patient laid face downward on the webbing strip, which may be covered with sheet wadding. The thighs are flexed and the feet rest on the floor so that the lumbar spine is flattened. Two pieces of webbing are passed over the mid-dorsal region from side to side and tied to the lower non-movable frame on each side. These furnish the resistance for the straightening of the spine, when the upper end of the frame is lifted, carrying with it the upper chest and head. The upper part of the frame is lifted after the patient is in place and as much force as seems advisable is exerted. This should never be pushed beyond the point of mild discomfort. Several stretchings are made, at first of a few seconds each, and the movable part of the frame again let down to rest the patient.

7. Pelvic machines (devised by author). These are used to fix the pelvis during exercises so as to more carefully localize them. It is obvious that unless the pelvis is fixed during trunk bendings and swayings, the exercise is a general one and not a local one. These machines are made of gas pipe and are screwed to the floor. They consist of an upright made in two pieces, one sliding within the other, on top of which is a horizontal arm, which may be tipped up or down, and to which is fastened two sliding arms so as to grasp a pelvis of any width. These arms are connected by a leather strap which passes about the pelvis and holds the patient firmly.

8. The chest weight, dumbbells and wands are used for general symmetrical and setting up exercises.

9. Schultess' machine. This machine has been used for recording the scoliosis cases. It is complicated and can be used satisfactorily by one person only, who should make all observations. The apparatus consists of an upright frame in which the patient stands, the pelvis being fixed by clamps and the sternum steadied by an adjustable rod. Behind the patient is a sliding bridge with counter weights which move up and down on uprights. Attached to this bridge is a pointer which moves forwards and backwards and sideways. The movements of this pointer, by an arrangement of weights and pulleys, are recorded upon two glass panels parallel to the sagittal and frontal planes of the body by means of pencils moving on paper attached to the glass panels. By tracing from below upward the marked lines of spinous processes on one panel, the antero-posterior curve of the spine is recorded, while on the other the lateral curve is simultaneously marked. By a longer pointer the lateral body outline is then traced in the frontal plane, after the position of the scapulæ has been recorded. The two pencils in use are then thrown out of

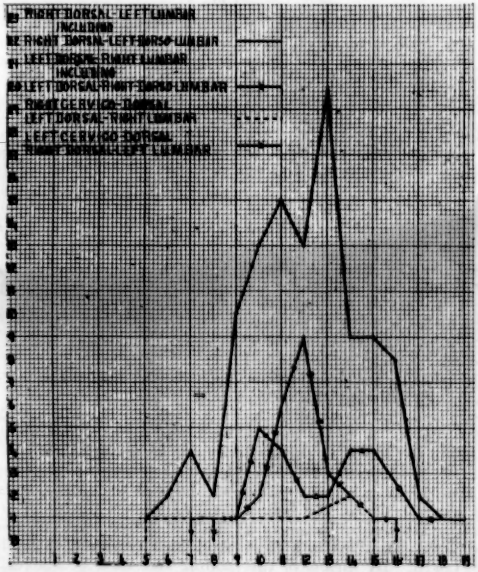

CHART V shows relations of triple structural curves.
(Figures at side show number of cases; figures at bottom give ages by years.)

action and by means of a third pencil, working on a glass plate on the sliding bridge, horizontal contours are recorded at three levels.

OCCURRENCE OF SCOLIOSIS.

I have made no attempt to take the figures for the clinic since its organization as a separate department, but have relied on the figures covering the period from October, 1903, to June, 1909. In three of these years the clinic was closed during the month of August, and in the other years during July, August and September was run at a very low level. The total number of cases during this time was 571. The total number of visits was 26,329, giving an average daily attendance of 46.07. There were boys, 130; girls, 441. This great difference between boys and girls is due to the probable fact that boys do not come to the clinic for treatment until the curves become severe, or until complications arise, while in girls the effects of scoliosis upon the figures are perceptible much earlier and treatment is sought to remedy conditions which in boys pass unnoticed. Statistics of clinics in various institutions show the same difference between boys and girls, whereas records from the examinations of large numbers of school children show about equal occurrence of scoliosis in both sexes.

AGE.

It must not be supposed that the appended charts show accurately the ages at which the scoliosis developed. Scoliosis is a deformity coincident with growth, and it probably begins in the early years of life. It has been noted as occurring from the first year up to the eighteenth year, but rarely develops afterwards. There is usually an increase in its frequency of development between the eighth and thirteenth years. Inaccurate parental observation makes it most difficult to establish any definite period of onset in the individual case.

INFLUENCE OF SHORT LEG.

A short leg either on one side or the other, except in rare cases, does not seem to play any definite part in the development of scoliosis of any one type. Out of 177 cases of total functional scoliosis, there were 37 cases with a short leg, the difference in length being about equally distributed on each side, and apparently affecting the development of the curve in no way.

ETIOLOGY.

I have made no attempt to classify these cases on an etiological or pathological basis, for at present our records are not complete enough, nor, even if they were, would it be possible to do so. At present the x-ray plays a great part in helping us to make a diagnosis of the curve, and it is a great surprise to me to find in a large number of cases anatomical deficiencies or variations of the vertebral column hitherto unsuspected.

RELATIVE FREQUENCY OF THE DIFFERENT FORMS OF SCOLIOSIS.

One hundred and seventy-seven cases out of the total of 571 showed a condition of functional scoliosis, 164 of these being the usual left total curve and 13 being the more unusual right total curve. A number of these showed also a co-existing condition of round back and forward shoulders. These conditions may be noted in the following Table I.

TABLE I.

Total or Postural Scoliosis.

Total,		37

Tracing as many of these functional cases as was possible after periods varying from several months to several years after having left the clinic, I found that 41 of them had developed definite structural deformities, varying more or less in degree. There are presumably others which have also changed into structural curves, but I have been unable to trace them for observation. These figures (see Table II) compare favorably with the series observed by Hess, who observed 86 cases of total functional scoliosis, of which 60 persisted as total scoliosis and 26 changed into structural curves.

	6

Chart I shows the totals of each class of case and also the relative number of boys and girls in each class.

Chart II shows the relation of the anteroposterior variations to each other with their occurrence by ages.

The other charts show the relations of the simple functional and compound structural curves to each other in their occurrence by age and frequency.

It may be noted that from eleven to thirteen years of age is the period of greatest frequency and occurrence, both in the functional and structural scolioses.

The relative frequency of the occurrence of these different clinical forms is in favorable relation to the records of other observers, and these curves may then be taken as showing about the usual relations and frequency of occurrence as ordinarily observed in the various hospital clinics abroad.

AN HISTORICAL NOTICE OF THE OPERATION OF CÆSAREAN SECTION FROM THE FIRST OPERATION TO THE MIDDLE OF THE EIGHTEENTH CENTURY.

BY CHARLES GREENE CUMSTON, M.D., BOSTON.

If we are to believe Pliny (Hist. Nat., Lib. 7, chap. 9), the Cæsarean operation was performed long before his time, or at least the first case, because he says: "*Enecta parente gignuntur sicut Scipio Africanus prior natus, primusque Cesarum a cæso matris utero dictus.*"

This sentence has been very differently interpreted by a number of writers; several have upheld that Pliny referred to Julius Cæsar, and they assure us that an incision was made in order to remove this illustrious being from the belly of his mother, but Bayle, in his famous Dictionary, unhesitatingly states that this is false, a fact which had been pointed out before him by Zonaras. It is evident that Bayle is quite right in opposing the inference that these writers have made on Pliny's text relative to Julius Cæsar, because, as he points out, Cæsar's mother Aurelia took great care of her son's education and died while he was waging war on the Gauls. However, it is possible that Aurelia survived the operation and, consequently, the opinion of those who have upheld that Cæsar was removed from his mother's uterus through an incision is not destroyed. Some have believed that the Cæsarean operation took its name from Cæsar, but, according to Pliny, it should rather be inferred that Cæsar took his name from the operation itself, because those who were borne by means of this surgical interference were, according to him, called *Cæsares aut Cæsones a cæso matris utero.*

If one is satisfied with the conjectures which naturally arise from the name of Cæsar and the remark made by Bayle, it would seem that one might conclude that the Cæsarean operation was performed on the living female, but these conjectures are far from being decisive, and there is no certainty that in these far-off times surgeons dared to have recourse to it for saving the life of the mother and child. On the contrary, it is to be pointed out that up to the last century the profession was extremely skeptical as to the success of this operation, and I have been unable to discover any other reports of this operation before the commencement of the sixteenth century.

The first case recorded is that related by Bauhin, which he attributes to a butcher who performed it on his own wife. In the year 1500 the wife of Jacques Nufer was pregnant with her first child and, feeling labor pains for several days, had several midwives come to deliver her. They made many attempts to bring about labor, but they were all useless, and as the patient experienced very severe pains, and as there no longer was any hope of relieving her, her husband said that if she would confide in him he would undertake an operation which, by the grace of God, might possibly succeed. His wife replied that she would undergo anything to be relieved. As the affair was a delicate one the husband asked permission of the President of Fravenfelden to undertake this operation; the Judge at first would not consent, but being informed of the condition of the woman, and the willingness of the husband to relieve her, he at last allowed the operation to be performed. The husband returned home and told the midwives that those of them who were sufficiently courageous to help him might remain in the room, but that those who were not must withdraw. After imploring divine help, he laid his wife on a table, incised the abdominal wall and then the uterus, after which he quickly extracted the child. Several sutures were placed in the abdominal wall. The wound healed happily without any complication, and several years afterwards the woman was delivered of two children, one becoming a judge at Siergershenfen and who was alive in 1583.

François Rousset, who lived at the end of the sixteenth century, appears to be the first writer who undertook to advise the operation on living women. His book, which was published in 1581, is really a masterpiece and has for title: *Traité nouveau de l'Hysterotomotokie ou Enfantement Césarien, qui est extraction de l'enfant par incision latérale du ventre et matrice de la femme grosse ne pouvant autrement accoucher, et ce sans préjudicier à la vie de l'un et de l'autre ni l'empecher la fécondité maternelle par après.* Paris, 1581.

In the first part of this book he first points out the utility of the operation when there is imminent danger for both mother and child in cases where delivery is impossible by the birth canal. Next he establishes the possibility of this operation by showing that wounds of the parts involved in the operation are not necessarily fatal. And, lastly, he goes into considerable detail of several obstetrical complications which are far more dangerous than the operation itself and which may be avoided if the operation is done. These complications he places under five headings. In the first he refers to women who, being pregnant and the child dying and becoming decomposed, has

caused death of the mother on account of uterine infection, and who might have been saved if this operation had been resorted to. In the second class he relates several cases of abscess of the uterus which were successfully opened by means of the actual cautery. In the third, he mentions several cases of ulcer of the womb (sic) which allowed the child to make its exit into the abdominal cavity, and was followed by abscess in the hypogastrium. This was opened without any danger to the mother. In the fourth he refers to several cases of amputation of the uterus performed with the knife, ligature or cautery and the women had lived. And lastly, in the fifth section he proves by several examples that a woman can conceive after this operation.

In the second part of his book, Rousset establishes the sureness of the Cæsarean operation and proves this by relating cases which had been given him from reliable sources, and, lastly, the operations that he advised to be performed.

These cases are seven in number. In the first, we have the history of a woman named Godard upon whom the operation was performed six times, all the children living. The patient died the seventh time she was pregnant because she could not obtain the services of the surgeon who had delivered her by the operation upon previous occasions. The second observation was that of a patient upon whom the operation had been performed three times by two surgeons by name Ambroise le Noir and Gilles le Brun. The author was desirous of seeing the patient, but learned that she had died shortly before from the plague which had ravished the town where she lived. The third observation is a letter written by Aliboux, a physician at Sens, in which he states that Jean Desmarais, a surgeon at Chastre en Berry, had performed the Cæsarean operation on his wife and that later she was delivered naturally of a daughter. The fourth observation is merely the simple recital of a similar operation told to the famous lithotomist of Paris, Laurent Colot, by Pelion, a physician of Angers. The fifth case refers to another operation which was quite as successful as the other four. In the sixth, Rousset says that he saw at the hospital of Châtillon, in company with Denis Armenaut, a physician of Gian, a woman who had on the right of the abdomen a hernia accompanied by a very long cicatrix, and having asked her the cause of the latter she replied that it was the result of an incision that had been made to deliver her and that the child was at that time seven years old. In the seventh observation he relates that, in 1556, a woman who had been four days in labor had been operated on successfully. Eighteen months afterwards her husband died, she married again and was afterwards delivered of a daughter, the labor being normal.

Some time before the publication of Rousset's book, Ambroise Paré gave to the world his work on surgery in which he strongly criticises the Cæsarean operation, the following being his exact words: "Or, je m'émerveille comme d'autres veulent affermer avoir vû des femmes auxquelles pour extraire leurs enfants, l'on auroit incisé le ventre non-seulement une fois, mais plusieurs; car telle chose pour raison n'est du-tout impossible à croire, entendu que pour donner issue à l'enfant, il faudroit faire une grande plaie au muscles de l'épigastre et pareillement à la matrice, laquelle etant imbue d'une grande quintité de sang, et y faisant une division si grande, il y auroit une très-grande hémorrhagie dont la mort s'ensuivroit; davantage après avoir consolidé la plaie, la cicatrice ne permettroit pas à la matrice de se dilater pour porter l'enfant; il y a encore d'autres accidents qui en pourroient advenir, et le pis une mort subite à la mere; et partant, je ne conseillerai jamais de faire telle oeuvre où il y a si grand péril sans nul espoir en parlant humainement. Toutefois on m'a assûré qu'un nommé Maitre Vincent, Chirurgien d'Hericy près Fontainebleau a fait cette périlleuse opération avec heureuse issue; la femme que l'on dit avoir été incisée, et ledit Maitre Vincent, sont encore aujourd'hui vivans: tant de gens d'honneur dignes de foi me l'ont affermé, jusqu'à même à me dire avoir vû faire l'opération et extraire l'enfant, que je ne veux ni ose les mécroire, mais cela étant, j'ose bien dire que c'est un vrai miracle de nature," etc.

The operation referred to by Paré is reported in detail by Schenckius, who says that the surgeon who operated was not from Hericy, but from Nemours; that the patient's name was Nicole Beranger and that the operation was performed in 1542; he adds that the child was in decomposition and that there was such little hope of saving the mother that the surgeon only placed a few sutures in the skin, so that there resulted a ventral hernia for which the patient was obliged to wear a support. Schenckius also says that he saw the woman nearly two years after the operation and that she had been delivered of a daughter by the natural route.

It would appear that Paré was not always opposed to the Cæsarean operation because in the first edition of Rousset's book is to be found an Approbation by De Monanteuil, Regius Professor of Mathematics and Dean of the Faculty of Medicine of the University of Paris, in which this physician greatly praises Rousset's work, and immediately below this Approbation is found: *J'atteste ce que dessus*: Ambroise Paré.

In 1582, Gaspard Bauhin made a Latin translation of Rousset's book, which had for title, *Exsectio foetus vivi ex matre viva sine alterutrius vitae periculo et absque faecunditatis ablatione, a Francisco Rosseto Gallice conscripta, a Gasp. Bauhino latine reddita et variis historiis aucta. Basil. 1582.* To this he added several operations which had been successfully performed in an appendix to the work. The majority of these observations were sent to Bauhin by Albosius and Saguyerus; others were taken from the writings of Mauritius Cordaeus and Felix Plater, while several new ones were given by Rousset himself. At the end of his translation Bauhin says that this operation was performed on a woman named Elizabeth Turgois, and that afterwards she was delivered normally of four children.

In 1590, Rousset published his *Dialogus Apologeticus pro cæsareo partu, in malevoli cujusdam Pseudoprotei dicteria. Paris. 1590.* In this work he considers all the objections which had been made by his adversaries, and even takes it upon himself to expose them in their proper light, which gives him occasion to enlighten and fortify his own way of thinking. He deemed it *à propos* to give the sources from which he had obtained his knowledge, and speaks of noted men, with whose commerce he seems to have been familiar. Had his poem not been so long it might have placed him among the distinguished Latin poets of his day, while the object that he had in view would have suffered in no way. He gives to the ancients all necessary justice which is due them from those who have carefully meditated upon their writings, but he goes beyond timid admiration, which limits itself to respecting these early masters, and neglects to employ their knowledge in acquiring new. He proves by happy discoveries, unknown to these great men, that the genius of medicine did not become extinct with them, and that if they had lived in his time they would have made his own proofs more complete. Nothing can be simpler or more solid than his reasoning concerning the necessity of the Cæsarean operation, and nothing could be clearer or more precise than the instructions he gives. He describes the operation with great clearness, likewise his reasons in its favor.

This Dialogue brought forth many severe criticisms on the part of a certain Marchant, a surgeon of Paris, who published a work entitled: *In Francisci Rosseti Apologiam Jacobi Marchant, Regis et Parisiensis Chirurgi Declamatio.* In the first part of this work, Marchant combats the Cæsarean operation with the same arms as those employed by Paré, and rejects the first observation given by Rousset as false and contrary to all the laws of the animal economy. He then takes up the history of the woman of Châtillon and points out that the cicatrix observed on her abdomen by Rousset was not sufficient proof for believing that the operation had been done on her. I will quote him in his own words. "Combien ne voit-on pas de cicatrices de plaies accidentelles & d'abcès au ventre, qui pourroient faire croire que ce seroit une suite de l'opération Césarienne? Les habiles Chirurgiens, toujours zélés pour le bien public et pour le soulagement des malades, ont saisi avec empressement votre nouveau système, et ont voulu eux-mêmes être convaincus de sa vérité. Guillemeau fut le premier qui trouva l'occasion de faire l'opération Césarienne à une femme qui souffroit depuis plusieurs jours des douleurs cruelles, sans espérance de pouvoir accoucher; il opéra en presence d'Ambroise Paré et de plusieurs autres Chirurgiens de l'Hôtel Dieu de cette Ville, mais la malade mourut cinq jours après. Paré, Carbonet, Brunet et Viard ne furent pas plus heureux dans plusieurs autres occasions qui se présenterent." He ends the first part of his work by an enumeration of many of the causes which may prevent a natural delivery, but without referring to many conditions in which a normal delivery is really impossible he has the pretention of upholding that a careful and skilled physician may overcome all these difficulties without having recourse to Cæsarean section, which, according to his way of thinking, always ends fatally.

Marchant's zeal carries him away in the second part of his book, and he no longer combats Rousset by logical reasoning, but gives himself up to insults directed against him, the book concluding by several satirical poems addressed to Rousset in which the criticisms are far from being what would be expected from a man of letters. It is quite true that much erudition, precision and distinctness of style are to be found in Marchant's writings, and from careful perusal one must admit the profound knowledge and skill of this surgeon.

Following these satires there is a letter by Guillemeau addressed to Rousset, in which he gives the reasons which caused him to oppose the Cæsarean operation in his works, but it must be said that this letter is written in much gentler language than that employed by Marchant, and by reading it the character of a friend is distinctly perceived. Guillemeau rather endeavors to dissuade Rousset from approving and favoring a practice which had had so little success in the hands of the most skillful surgeons of the time, but Rousset, still assured of the correctness of his cause, replied the same year with much erudition to Marchant, employing observation as the surest means to refute his adversaries. As a proof of this I would refer to an observation taken from the Latin edition of Rousset, which ends in these terms: *Hæc anno Domini 1573 diligenter observavi, et in Adversariis meis annotavi.*

It is apparent that the Declamation of Marchant and some unfortunate results following the operation were the means of preventing its further performance, because Guillemeau expressly says in the fourth book of his "Chirurgie," chapter 28, that "ce qui determina M. Paré à se desister et retracter de cette operation, aussi-bien que le College des Chirurgiens et la plus saine partie de la Faculté de Médecine de Paris, dans la question qui fut agitée par feu M. Marchant dans ses deux Declamations qui'il fit, lorsqu'il eut l'honneur de passer Maitre Chirurgien de Paris."

It is evident that these disputes were both for and against the operation; those published by Rousset show that it was not infrequently performed successfully, while the cases related by his opponents proved to the mind of the profession that the operation was dangerous, and undoubtedly it is for this reason that it was not placed among the current operations of surgery of the times. Rousset, however, continued his work in order to reassure the profession, and after considerably extending his researches in reference to this operation, he published, in 1590, a Latin edition of his work which was far more extensive than his first, its title being: *Caesarei partus assertio Historiolog. Paris. 1590.*

Besides the new and good reasons that he adds to those he had already given, he increases the value of the book by several new case-records in which a successful outcome had occurred. The first was the history of a woman upon whom the

operation had been performed in 1576. The child was dead and undergoing putrefaction. Some time later the patient again became pregnant and was delivered naturally. The second case was taken from a letter written to Rousset by Vertunianus, a physician of Poitiers, in which the latter tells of a woman who was delivered in this way and who recovered perfectly.

The third case was that of a woman whose child had succumbed *in utero*. This occurrence had happened some time before and every method known at the time had been employed in order to deliver her. As she was in a very critical condition, the surgeons decided to perform the Cæsarean section, and as soon as the uterus was opened a large quantity of fetid matter escaped. The patient suffered a great deal during the extraction of the child because the incision was hardly large enough to allow it to pass. However, no accident occurred, hemorrhage was only slight and much purulent matter came away with the lochia. Five weeks after, the patient was able to go out, and since this operation she had been happily delivered of five children. The fourth operation was performed successfully in the year 1580 by a surgeon named Jacotin. Rousset makes the remark that he saw this patient and that this surgeon told him that he had operated successfully upon two other women. The fifth and last case is the history of a successful operation performed in 1582, and the statement is made that the surgeon who performed it was not particularly dexterous, although he succeeded. Rousset, in his own words, says: "Haec femina secta fuit a Joanne Luca tunc parum sobrio; cui tunc bene poto si hoc non male successit quid ei non est sperandum, qui sobrius et mentis compos arte duce eo accedet?"

Scipio Mercuri, a surgeon of Rome, published, in 1604, a dissertation on obstetrics having for title "*La Commare Orucoglitrice.*" In this work he relates cases of successful Cæsarean section, and advises that this operation should never be neglected in those cases where delivery is otherwise impossible. This author relates that at one time, being near Toulouse, he saw two women who had undergone the operation and that one of them had had children afterwards. He makes the rather remarkable statement that, in his day, this operation was almost as common in France as bleeding was in Italy for headache.

The writings of Schenckius refer to a letter from Albosius in which the latter states that he had performed the operation successfully upon one occasion.

In his work entitled, *Libro Observ. de morbis mulier*, Roonhuisen, a surgeon of Amsterdam, makes the statement that a physician of Bruge, by name Sonnius, had performed the operation seven times upon the same woman.

A famous Swedish physician, Olaus Rudrecius, saved his wife's life by this operation, which he performed himself, while Thomas Bartholini relates in his *Hist. Anat. Cent.* that when he was at Paris he knew the wife of a surgeon upon whom the Cæsarean operation had been done five times. In Theophile Renaud's work, *De ortu infantium contra naturam per sectionem Cæsaream, autore Theoph. Renaudo Societ. Jesu Theolog. Lugd. 1637*, three operations with a successful outcome are recorded. In the first he relates the testimony of the famous surgeon, Louis Panthot, who assured him that in the month of April, 1627, a woman near Lyons, after having suffered labor pains of great intensity for several days, was at length happily delivered by the Cæsarean operation. In the second case he states that a Jesuit had seen at La Flèche a woman who certified that she had submitted to the operation three times, and also that the Jesuit personally knew the surgeon who had operated. The third case is taken from a letter from Pellaire, a physician at Maurienne, in which it is stated that this operation was done successfully six times on a woman living at Ville d'Auçois.

In 1692, Saviard published in the *Journal des Sçavans* the case of a dressing that he had applied for a ventral hernia following an incision for Cæsarean section fourteen years previously. The patient finally died, and an autopsy was performed in the presence of several surgeons, there being found a cicactrix in the uterus, comprising the entire thickness of the walls of the organ and corresponding to the incision in the abdominal wall. This author adds that the surgeon who had performed the operation was obliged to leave on account of the bad treatment he received from the relatives of the woman, but it would appear, however, that Saviard did not know the real motive for this flight, because in the *Journal* for the month of June, 1693, it is stated that, being a Calvinist, he had considered it *à propos* to leave hurriedly, as many other Protestants had done, on account of the trouble which was preparing against those who had adopted the reformed religion.

In the same *Journal* are to be found two cases recorded by Jobert concerning two Cæsarean operations performed on a woman twenty months apart. The patient recovered perfectly and the author adds that the child which was delivered at the first operation was still living and presented a small cicatrix on the lower jaw caused by a slight cut it had received from the surgeon's knife at the time of delivery.

In 1693 a woman had been in labor for a long time, the midwife had attempted to deliver her by all known means and finally succeeded. A very severe complication resulted in the form of a vesico-vaginal fistula. The patient, in order to obtain relief, resorted to quacks, but their work only resulted in the production of a vaginal tumor which completely filled the canal. In spite of this the woman became pregnant again and when labor set in she was attended by Lankisch, a physician of Zittaw, who advised a Cæsarean section, which was successful as far as the mother was concerned. The account of this case is to be found in *Acta erudit. Lips. ann. 1693.*

In his *Dissert. du partu Cæsareo, Vitebergae edita anno 1695*, Vaterus mentions a similar operation which appears to have been quite as successful. The patient on whom it was performed had the entire vaginal cavity filled by a vegetating mass

following an ulcer (probably cancerous), so much so that the end of the little finger could hardly be made to enter.

In 1707, Ruleau, a surgeon at Xaintes, published a dissertation on the possibility and necessity of the Cæsarean operation. He brings up nearly all the reasons given by Rousset in order to prove how very necessary this operation is, and speaks of a successful case which occurred in his own practice. The patient had been in labor with severe pains for five days, and vaginal examination showed that the pelvis was so deformed that two fingers could hardly be introduced into the vagina. He, therefore, resorted to Cæsarean section, with the result that there was no hemorrhage, the lochia was discharged through the wound and the patient recovered nicely.

De la Motte relates in his work on obstetrics a similar case. A poor woman had suffered for three days and the child presented by the arm. The midwife who attempted to deliver the patient tore the arm away. A surgeon was called and, finding much difficulty in delivery, performed Cæsarean section, withdrawing a dead child, and then closed the abdomen with several sutures. The cure of this poor woman was, so to speak, left to the care of nature, because the surgeon saw her only very infrequently, leaving the care of the dressings to the husband. The wound suppurated, but in spite of this the patient recovered.

In 1739 the Académie Royale de Chirurgie caused a woman living in Guise, who had undergone the Cæsarean operation, to appear before it for examination. This patient had been in labor for three days and the midwife, being unable to deliver her, called a surgeon. He tried all the known means to deliver the woman but unsuccessfully, and finally the patient begged the surgeon to operate. The surgeon was astonished by this request and refused to perform the operation because he had never heard of it. However, pressed by the prayers of the patient and her husband, he finally consented. He made a longitudinal incision in the skin and muscles reaching to within three fingers' breadth of the umbilicus. As the intestines came out the surgeon had the husband hold them back with his hands. He then opened the uterus, making an incision sufficiently large for the introduction of the finger and then, feeling the movements of the child, he enlarged it sufficiently to extract the child and placenta. The incisions of the uterus and abdomen were united by a few sutures and then an ointment composed of fresh butter and chimney soot was applied to the wound. Three days after the operation the sutures broke away, but on account of the pain the patient would not allow the surgeon to introduce new ones. The lochia made its exit by the wound, which for several days was livid; afterwards it became crimson and was entirely healed at the end of three weeks. It would appear that during the entire illness the woman did not seem to be in danger, because she nursed the child. After this operation she had four children by the normal route; three were born dead, while the fourth was alive when the patient came to Paris.

The famous surgeon, De la Peyronie, relates the case of a woman twenty-five years of age who was delivered of her first child successfully. As she could not be delivered in her second pregnancy after a long labor, a surgeon by the name of L'Amiral was sent for, who made an incision on the left side of the hypogastrium and delivered the child and placenta. The mother recovered in fifteen days and the child was still living at the time the patient was seen. Several years after the operation the woman was again pregnant; the labor pains were severe, long and without effect. The same surgeon again performed the Cæsarean section.

Urban reported the following cases to the Académie de Chirurgie. A surgeon named De Thise, living at Bure, had performed during the last eight or ten years, and with success, the Cæsarean operation on three women. The first patient lived in the Duché of Luxembourg; she recovered perfectly and had other children afterwards. The second patient lived at Rochefort and died two years after the operation from colic. The third lived at Ave in the Duché of Bouillon. The Cæsarean section was done, convalescence was long because the patient was taken with violent coughing spells which caused the sutures to give way. One of the members of the Académie saw the latter case and wrote a letter to Houstet, dated Sept. 7, 1741, in which he says, "Qu'il étoit survenu à cette femme huit mois après l'opération une hernie ventrale de la grosseur et la forme d'un chapeau; que cette tumeur occupoit toute la region ombilicale droite; que l'enfant avoit vécu trois mois et demi, et que la malade avoit été guérie au bout de trois semaines; cette femme a eu trois enfans depuis l'opération."

A surgeon by the name of Brou, being unable to deliver a woman, performed the Cæsarean operation in the presence of her husband and the village priest. From his incision he withdrew a female child, who, at the time of writing, was eighteen years of age. The skin and muscles were united by a few sutures, which gave way after several days, but, nevertheless, the wound healed very well and some time afterwards De la Faye being in the neighborhood asked to see the woman and found a long cicatrix in the abdominal wall which had given rise to a large hernia. He found that the hernia was a little over thirteen inches long, ten inches wide and that the cicatrix was eight inches in length, while the distance from the umbilicus to the cicatrix was five inches.

Noyer reported a case to the Académie de Chirurgie of a woman successfully operated on on April 17, 1726. The patient was thirty-five years of age and he extracted a child which had been dead for several days. Several sutures were inserted and seventeen days later the cicatrix was perfect. This woman became pregnant later and after a long labor she sent for Noyer to operate again, but he was absent and she died. The patient had been delivered normally three times before the operation.

In the Histoire de l'Académie Royale des Sciences for the year 1730 is to be found the following

case. In 1723, Mme. Flandrin, a midwife in the town of Bulle in Fribourg, was called to attend a patient forty-eight years of age and pregnant for the first time. The head presented, but the pelvis was very narrow. Having tried for a day and a night all possible means of delivery, and being unsuccessful, she sent for Dr. Michel, who ordered a fortifying treatment, but on the fourth day, as the patient was still in labor, the doctor advised the midwife to draw the child with a crochet, and if this could not be done, to remove it piecemeal. As this was not successful, there alone remained the Cæsarean operation, which was decided on on the seventh day. It was done by the midwife herself with great courage and skill. The patient was delivered without any accident.

Helvetius, who communicated the above case, also produced a letter from Dr. Michel stating the facts to be true.

The wife of Dr. de Presseux, a physician of Spa, became pregnant for the first time at the age of thirty-five. When the labor pains set in a midwife was sent for, who informed the husband that the child was in good position. The pains continued for two hours and the membranes ruptured. Dr. de Presseux, perceiving that his wife suffered a great deal and that labor did not advance, made an examination himself and was greatly surprised to find that the presentation was a breech. He at once sent to Liege for a surgeon by the name of De Blierre, who arrived the next day and with the husband worked for eighteen hours endeavoring to perform version. As the child was dead and as it was impossible to change the position, the surgeon proposed the Cæsarean operation as the last resource. The husband was, in the first place, opposed to it, suggesting an instrumental delivery, but the surgeon replied that this could not be done because he had brought no instruments for it. As the patient was extremely weak, the husband finally consented. An incision was made and when the abdomen was opened the bladder was found tremendously distended, so much so that it almost covered the uterus, and as the size of the bladder prevented the surgeon from easily incising the uterus, he punctured it to the side of the fundus and emptied it completely. The uterus was then free and was opened and the child extracted. A few sutures were put in the muscles of the skin. The operation was not followed by any hemorrhage, the lochia passed by the vagina and was small in amount. Fever occurred several days after the operation, but was controlled by proper treatment. At the end of three weeks the sutures were removed and a little fecal matter came out at a point where the wound was not quite healed. By the application of certain remedies intended to accelerate cicatrization, the wound rapidly closed. This operation was done on the first day of the year 1738, and on Dec. 24, 1740, she was happily delivered normally of a female child.

In the month of April, 1740, Dr. Soumain was asked to see a woman aged thirty-seven years of age in the seventh month of pregnancy. At the first visit the patient appeared to be very worried because she was aware that from infancy her body had been deformed. During the following visits this surgeon had the opportunity of examining the patient and found that all the bones were deformed, principally the lower part of the spine and the pubic bones, which were so close together that there was not more than a space of two inches. Soumain saw the unfortunate outlook and was ready for action. On the seventh of June labor pains commenced, the membranes ruptured and the amniotic fluid was expelled. Soumain examined the patient and found that no progress was being made. From the seventh to the tenth of the month the condition remained the same, the pains caused a slight dilatation of the cervix, which only showed that it would be an impossibility to deliver the patient by the vagina. Therefore, Cæsarean operation was decided on in consultation with Drs. Bourgeois, Puzos, Souchay, Verdier, Gervais, Gregoire, Iard, Chauvin and La Fitte. After careful examination they all came to the conclusion as to the impossibility of delivery, and were of the same opinion as Soumain. I would point out that the above men were the most illustrious in the profession at the time.

The patient was placed on the edge of her bed, the head and thorax being a little higher than the rest of the body. It is stated in the report that there was a "scirrhous hardness of the omentum" on the right side, so, therefore, the left side was chosen for the incision, all the more so because on this side the uterus bulged out on account of the oblique position of the child. Soumain incised the skin, muscles and peritoneum, and as soon as the latter was opened the intestines protruded, but were retained within the abdomen by the hand of one of the consultants. The uterus was then easily seen. As the amniotic fluid had been expelled, and as the uterus had retracted on the child, it was opened with great caution. The child presented by the lower part of the back and upper part of the breech. After extraction the cord was tied and, aided by Puzos, the placenta was removed. After this the intestines were replaced and the wound closed with a few sutures and the proper dressings applied. The hemorrhage which followed the detachment of the placenta was slight. A few days after the operation suppuration became established, the pus became laudable, and forty-seven days afterwards the patient was able to go to church. The child measured twenty inches in length and survived ten days. It was afterwards reported that it died on account of neglect on the part of the nurse.

I will not refer to any other writings on the question of Cæsarean section because all the authors resorted to the same reasoning as did Rousset and, therefore, this would be merely a repetition, but it may be said that many were greatly in favor of it. At a later date I hope that I may be able to publish a second paper dealing with the history of this operation from the middle of the eighteenth century to the present time.

A NEW mission hospital was recently opened at Pensacola, Fla. — *Jour. Am. Med. Asso.*

LACTIC ACID BACTERIA; WHAT THEY ARE AND WHAT THEY ARE SUPPOSED TO DO.*

BY ARTHUR I. KENDALL, PH.D., BOSTON.
(From the Department of Preventive Medicine and Hygiene, Harvard Medical School.)

From the earliest historic times the drinking of sour milk has been practiced by many nomadic and semi-nomadic tribes. Originally these people undoubtedly consumed milk in the fresh state, unacted upon by bacteria, but the advantages of soured milk must early have been appreciated.

Milk that has soured in a proper manner can be kept for some time without further change and yet retain its palatability, a point of great importance in those countries where no other means of preservation are available. Furthermore, any surplus milk can thus be rendered fit for future consumption, and undoubtedly this purely economic factor has been potent in popularizing this natural method of preservation.

In certain instances, peculiar methods have been gradually evolved to bring about this souring, and the well-known Kephir granules may be mentioned as a familiar example. Kephir granules consist essentially of lactic-acid-producing bacteria and yeasts enclosed in a coagulum of casein. The lactic acid bacilli ferment the lactose of milk, forming lactic acid, while the yeasts cause a secondary alcoholic fermentation which gives increased palatability to the finished product.

Kephir granules and similar ferments, then, are to be regarded as "starters," and our present-day use of starters for ripening cream and of dispensing lactic acid bacilli in tabloids is in reality the direct descendant, refined to be sure, of the procedure established centuries ago.

Little interest was manifested clinically in these soured milks until Metchnikoff and his school published their observations on the relation of bacterial putrefaction in the intestinal tract to premature senility, and the employment of lactic acid bacilli to counteract this pernicious activity. About this time, Grigoroff, a student in Massol's laboratory, called attention to the many instances of longevity among the Bulgarian peasants, and to the fact that sour milk forms an integral part of their diet. Other observations of a similar nature have been collected, and it is upon evidence of this circumstantial nature, rather than upon well-planned and carefully executed conclusive experiments, that the whole subject of lactic acid therapy rests at the present time.

It is the purpose of this paper to outline, briefly, the salient features of lactic acid therapy: what the lactic acid bacteria are, the kinds of bacteria employed in intestinal therapy, the conditions under which they may be expected to act in a salutary manner, and the nature of this action.

Lactic acid therapy consists essentially in administering by mouth living cultures of lactic acid bacilli, either in milk soured by their action or as tabloids, together with some easily fermentable carbohydrate. The bacteria ferment the carbohydrate in the alimentary tract, producing lactic acid.

* Read at the meeting of the New England Pediatric Society, May 21, 1910.

The object of this treatment is to restrain the activity of certain proteolytic (putrefactive) bacteria in the intestinal tract. These proteolytic organisms act upon protein and protein decomposition products, forming aromatic substances, indol, skatol, phenol, cresol and aromatic oxyacids, and these aromatic bodies in turn are absorbed, in part at least, and act as slowly cumulative poisons to their host. Such, at least, is the generally accepted hypothesis. According to Metchnikoff, who elaborated this method of treatment, the putrefactive bacteria are largely anerobic in character, and are localized in the large intestine. The lactic acid bacteria, on the other hand, are non-proteolytic in nature and find their most suitable environment in media containing fermentable carbohydrate, which they break down, producing lactic acid in considerable amounts. These organisms do not form putrefactive products, and, indeed, under such conditions they metabolize only enough protein to satisfy their nitrogen requirements.

There are many kinds of bacteria which form lactic acid, but in the restricted sense in which the term "lactic acid bacilli" is used in intestinal therapeutics, only those organisms are regarded as true lactic acid bacteria which form lactic acid and smaller amounts of the lower fatty acids, but which do not form putrefactive products from protein, and which do not produce gaseous products from the fermentation of carbohydrate. In addition to the lactic acid bacteria of sour milk, there are normal lactic acid bacilli in the intestines of man and the higher animals. The intestinal lactic acid bacteria are very similar, so far as their nutritive requirements are concerned, to those of sour milk, but there is one rather striking difference between the two classes. The sour milk bacteria usually become localized in the small intestines of man and animals, while the intestinal lactic acid bacilli, particularly *B. acidophilus*, which is the best known, find their most suitable habitat in the large intestines. The significance of this difference will be brought out later.

To arrive at a clear understanding of the nature of the antagonism between the lactic acid bacteria and the intestinal putrefactive bacilli will necessitate a discussion of the metabolism, chemistry and conditions favoring the respective development of the two types of organisms.

We will consider the proteolytic bacteria first.

There are several conditions favoring the vegetative reproduction of these putrefactive microbes in the alimentary tract:

1. An excess of protein in the diet. Animal protein is far more easily attacked than vegetable protein.

2. Protein in which decomposition has commenced.

3. Imperfect gastric digestion or gastric stasis. In these conditions, food is passed into the intestines in a state predisposing to putrefaction.

4. Intestinal stasis. Any condition retarding the rate of passage through the lumen of the intestines will tend to increase the activity of putrefactive processes.

5. Impaired intestinal absorption of protein. If the absorption of protein is slow, putrefaction of a bacterial nature will be increased, since the food supply of these bacteria is increased.

Certain other factors tend to limit bacterial putrefaction in the intestinal tract.

1. Rapid absorption of protein and the products of protein digestion, by reducing the available food supply of intestinal microbes, tends automatically to limit putrefactive processes.

2. Factors causing the rapid passage of food through the alimentary tract, as cathartics, and certain forms of spontaneous diarrheas.

3. Starvation, by lessening the food supply of bacteria, inhibits their activities.

4. The activity of lactic acid bacteria in a medium containing fermentable carbohydrate.

5. The presence of carbohydrate alone is not infrequently associated with a diminution of intestinal putrefaction, as shown by the decrease in the amounts of aromatic substances in the urine.

It would appear, then, that there are two distinct types of bacterial activity in the intestinal tract: the first, essentially putrefactive; the second, fermentative. The putrefactive organisms are essentially proteolytic and require protein in their dietary. They do not develop in media containing fermentable carbohydrate in the presence of bacteria capable of forming lactic acid from this sugar. The fermentative bacteria (lactic-acid-producing bacteria), on the contrary, thrive best in media containing sugars. They utilize only small amounts of protein and do not form typical putrefactive products in appreciable amounts. These organisms are distinctly antagonistic in their action upon proteolytic bacteria in saccharine-containing media.

In addition to the proteolytic bacteria and the fermentative bacilli of the lactic acid type, there is yet a third group of intestinal organisms, a group which is facultative with respect to protein and carbohydrate requirements. That is to say, they can develop well in media containing protein, or in media containing carbohydrate with only small amounts of protein. This facultative group is by far the largest of the three mentioned and includes many of the best-known and most thoroughly studied of the intestinal flora. As a familiar example, *B. coli* may be mentioned, and inasmuch as this organism illustrates in a striking manner a fundamental but by no means generally recognized principle of bacterial adaptation in metabolism, it will be well worth while to consider the products of vital activity of this organism in detail. The facts to be brought out are also of the utmost significance in relation to lactic acid therapy.

It appears to be a fact that the facultative group of which the colon bacillus is a member can accommodate their metabolism to different classes of foodstuffs in a perfectly definite manner. When they are grown in protein media, their products of vegetative activity are, chemically speaking, typical of protein putrefaction. If, however, they are grown in media containing carbohydrate, the products formed are almost invariably those characteristic of fermentation. In other words, the facultative bacteria combine, under the conditions stated, the attributes of both the proteolytic (putrefactive) and fermentative organisms.

The details of an actual experiment will elucidate this principle most clearly:

Two portions of meat-juice-peptone bouillon were prepared, each of exactly the same composition and reaction. To one portion 1% of dextrose was added, and the two flasks were then inoculated with the same strain of *B. coli* and incubated a week at body temperature. At the end of that time the contents of the flasks were analyzed chemically.

The flask containing no dextrose was foul-smelling, alkaline in reaction and contained ammonia, indol, skatol, phenol and aromatic oxyacids. In other words, this was a typical protein putrefaction.

The contents of the flask containing dextrose were acid, of an appetizing odor, and contained, besides carbon dioxide and hydrogen, which were evolved, lactic acid and smaller amounts of acetic and succinic acids. This decomposition represented a fermentation, although of not the typical lactic acid type, since gaseous products were formed in addition to lactic acid. The simple addition of dextrose, then, has changed the type of bacterial decomposition from the putrefactive type to the fermentative type. This protective action of the carbohydrates on the putrefaction of protein is also found to hold in the case of monkeys. The addition of sugars to the diet of such animals, previously on a strict protein regimen, results in the disappearance of aromatic substances from their urine.

The explanation of this phenomenon is not as simple in the intestinal tract as in the test tube, where we are dealing with single organisms, however, and there are two distinct phases to be recognized. First, the presence of fermentable carbohydrate tends to change the character of the metabolism of the facultative bacteria from the proteolytic to the fermentative type. This in itself would eliminate from the urine the amounts of putrefactive products attributable to their activity when the animal was fed on protein. In addition, however, there is found to be a distinct decrease both in the numbers and vitality of the obligate proteolytic organisms, accompanied by a corresponding increase in the normal intestinal lactic acid bacteria.

The addition of carbohydrate to the diet of animals previously on a strict protein diet, then, tends to diminish intestinal putrefaction, judging from the disappearance of aromatic bodies of putrefactive origin from the urine. These aromatic bodies are considered by most authorities to be the most available criteria upon which to form a judgment of the amount of protein putrefaction of bacterial origin in the intestinal tract; they have been so regarded almost universally in lactic acid therapy. If this be the case, it is perfectly possible to explain the reputed beneficial effects following the introduction of carbohydrate

and of artificial cultures of lactic acid bacilli without the intervention of these bacteria at all, since the change in character of the metabolism of the facultative organisms and the suppression of activity of the obligate proteolytic bacteria, as outlined above, would remove from the urine the substances indicative of putrefaction.

Having thus outlined, in a brief manner, the salient facts governing bacterial development in the intestinal tract, it will be possible to consider more closely the specific action of lactic acid as they develop in the intestinal tract.

One of the best-known and widely used sour milk organisms is *Bacillus bulgaricus*. These organisms have been shown to localize themselves in the small intestine. On the other hand, *Bacillus acidophilus*, the most thoroughly studied intestinal lactic acid bacteria, is found in the large intestine.

If the supposition that proteolytic activity is most marked in the large intestine be true, it follows that *Bacillus acidophilus* rather than *Bacillus bulgaricus* would be the more efficient organism to utilize in attempts to control this proteolytic activity, since both these organisms produce considerable amounts of lactic acid in suitable media. The lactic acid generated by *B. acidophilus* would be liberated in the midst of the putrefactive bacteria, while that elaborated by *B. bulgaricus* must be carried with the intestinal contents to the large intestine from the small intestine. Lactic acid is absorbed from the intestinal tract and burned in the body, so it is evident that the amount available in the large intestine would be problematical if the bulgarian ferment were relied upon.

In spite of the accepted idea that the seat of bacterial activity upon protein is localized in the large intestine, the writer believes that there may be a very decided bacterial decomposition of protein in the small intestine as well. This decomposition certainly takes place in experimental animals under certain conditions, and, in the case studied by the writer, this breakdown of protein was brought about by the symbiosis of an organism of the subtilis group acting with the colon bacillus. Since the protein acted upon was milk, it may be interesting to outline the process. A subtiloid bacillus of intestinal origin was allowed to grow in milk; a moderate amount of peptonization of the casein took place. A colon bacillus of similar origin coagulated the casein and produced a small amount of gas as well. If, however, after the subtiloid bacillus had partially peptonized the milk, the colon bacillus was inoculated, there was a further liquefaction of the casein, and a large volume of gas was liberated. It is absolutely essential that the bacteria act in the order mentioned to bring about the desired result, and it is a significant fact that this same order of the two types is met with in the alimentary canal.

The symbiotic action of these two organisms, acting in definite sequence, therefore, causes a greater liquefaction of the casein and the formation of much more gas than the sum of their separate activities. This action is prevented by the presence of fermentable sugar and lactic acid bacteria, since this process is largely proteolytic and proteolysis cannot take place in the presence of rapidly developing lactic acid organisms.

From what has been stated above, we may summarize the effects of lactic acid therapy as follows;

1. Objectionable proteolytic activity, resulting in the absorption by the host of aromatic substances derived from protein decomposition by the action of proteolytic bacteria, may take place in the intestinal tract.

2. These aromatic compounds may be formed in the small or large intestines by the facultative or obligate proteolytic organisms.

3. An excess of protein in the diet of the host, or any factor causing stasis or impaired absorption of protein, appears to be the direct cause of this condition. The result is an unusual amount of available food which stimulated the development of these proteolytic intestinal organisms.

4. The addition to the diet of easily fermentable carbohydrate, together with the restriction of the protein, is of material assistance in reducing the output of these putrefactive products in many instances.

5. The beneficial action of the carbohydrate is a twofold one: First, the character of the metabolism of the facultative organisms tends to change from the putrefactive to the fermentative type, eliminating from the urine the putrefactive products referable to their activity; and, secondly, the lactic acid bacilli, either those given by mouth or those normally present in the intestinal canal, or both, proliferate rapidly, forming considerable amounts of lactic acid from this carbohydrate and inhibiting the further development of the obligate proteolytic organisms by rendering the medium in which there are growing unsuitable for continued development.

6. The proteolytic bacteria may be producing their harmful effects either in the small or large intestine; in the former case, the introduction of organisms of the bulgarian type may reasonably be expected to be of benefit, since we have seen that they tend to localize themselves in the small intestine. If, however, the proteolytic process is of large intestinal origin, the normal lactic acid bacilli of the acidophilus type are indicated. If there is reason to suspect that these normal intestinal lactic acid bacilli are enfeebled in their action, or absent, it will be necessary to feed fresh cultures by mouth, or introduce them per rectum.

7. While the primary object of introducing lactic acid bacilli is to inhibit the objectionable activity of proteolytic organisms, it is possible, and, indeed, experiments seem to indicate, that in addition to the formation of lactic acid, other products associated with their development may be formed which also act beneficially. The nature of these products, and the character of their beneficial action, however, is not definitely known.

In young children, more particularly those fed upon cows' milk, we may conceive of three distinct types of bacterial activity of an undesirable nature in the alimentary tract:

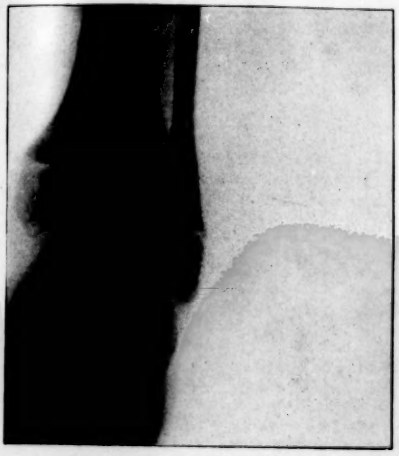

FIG. 1. X-ray, antero-posterior view, showing fracture through epiphysis.

FIG. 2. Lateral x-ray of same foot.

FIG. 3. Tracing from normal x-ray, showing outline of epiphyseal cartilage.

1. A true proteolytic type, characterized by the formation of putrefactive products, such as indol, phenol and oxyacids.

2. A mixed putrefactive and fermentative process, in which proteolytic and facultative organisms act symbiotically, producing through their symbiotic activity considerable amounts of gas and destruction of protein (casein). An example of this kind has been mentioned in which the colon bacillus and an organism of the subtilis group energetically destroyed milk.

3. A true fermentative type, in which there is an unrestrained overgrowth of true lactic acid bacilli. Salge has shown that in certain of his cases an enteritis resulted when the normal intestinal lactic acid bacilli of the acidophilus type proliferated to an unusual degree.

One not infrequently sees indications of this in infants whose diet has been for some time composed largely of Malt-suppe or similar preparations. There is developed a gradually increasing intolerance for this food, and bacteriological examination of such cases not infrequently reveals the fact that *B acidophilus* is present in greatly increased numbers.

Our knowledge of the whole subject of the application of bacteria in intestinal therapy, however, is still far too fragmentary to warrant a discussion of the treatment of these cases. All that can be legitimately done, and all that this paper hopes to accomplish, is to bring together, to analyze and to summarize our present knowledge of this subject.

FRACTURE OF THE LOWER EPIPHYSIS OF THE TIBIA, WITH A REPORT OF A CASE.

BY ARCHER O'REILLY, M.D.,
Instructor of Orthopedic Surgery, St. Louis University Medical School.

FRACTURES of the lower epiphysis of the tibia are comparatively rare, or at least they have not been recognized and reported. In looking over the literature, the author has been able to find reports of only two cases, one by Coolidge[1] and the other by Feiss.[2]

Coolidge's case is one of a boy who fell and caught his foot in an iron fence. The injury is referred to as an epiphyseal separation. The x-ray and the position of the foot show a deformity very similar to the condition in the case that I am about to report. The x-ray, however, having been taken several years after the accident, does not show the actual injury. The case reported by Feiss is very similar to Coolidge's case, but the deformity is more marked owing to the growth of the fibula. In both cases the x-ray shows an almost identical deformity in the tibia.

The history in these cases was very similar; there was a severe wrench at the ankle-joint and the foot was twisted laterally. Signs of fracture were present, but accompanied with little pain. At first the result was good, but deformity developed later, due to disturbance in the growth of the tibia, while normal growth in the fibula continued. In the case here presented, there is also a history of a violent injury, with inversion of the foot, and of a fairly good immediate recovery with increasing deformity later.

The marked similarity in the deformity resulting in these cases impressed me, and on studying the x-ray pictures it appears as if the anatomical structure of the bone and shape of the epiphyseal line might account for the similarity and the fact that the fracture apparently always takes place at the same point. The normal epiphyseal line is not, as a rule, straight, but in a number of cases curves upward near the internal malleolus, as is shown in the accompanying cut. Moreover, the articular surface of the astragalus is more or less pulley-shaped. Grey describes the superior surface as follows: "The superior surface presents, behind, a broad, smooth, trochlear surface for articulation with the tibia. The trochlea is broader in front than behind, convex from before backward, slightly concave from side to side." As will be seen in the cut, this internal comes a short distance outside of the up curve in the epiphyseal line. It seems probable, then, that any violent injury tending to invert the foot when the epiphysis had not yet become united would bring this inner ridge of the astragalus in contact with the epiphysis immediately below and slightly internal to the upward bend in the epiphyseal line. The greatest force of the blow would come at this point and apparently tends to force the epiphysis up into this hollow, giving the characteristic deformity.

It is remarkable how closely the x-ray in my case resembles those in both Coolidge's and Feiss' cases. The only difference is that my case is more recent and for that reason shows quite distinctly the line of fracture, nor does it show the amount of overgrowth of the fibula shown in the other cases. I am induced to publish this case because it seems to give some suggestion as to the mechanics of the deformity, and because the x-ray shows the condition so clearly.

W. X., boy, fourteen, was seen in August, 1909. Complained of weakness in the ankle and said that foot had a tendency to turn in. Did not complain of any pain.

Family history. — Fair.

Past history. — General health good. When seven years old, ran a needle in right foot. Several abscesses resulted, some necrotic bone removed. "Foot has been weak ever since." (Fragment of the needle can be seen in x-ray.)

Present illness. — Three years ago a horse fell on the right foot. The ankle was swollen and painful, and the patient was laid up in bed for a week. Used leg after that without any protection. Ankle has been weak ever since.

Physical examination. — General condition good. Well nourished. Color good. Head, neck, throat, heart, lungs normal. All joints and limbs normal except the ankle. Right foot in a varus position. External

[1] Coolidge: Fracture Lower Epiphysis of Tibia. BOSTON MED AND SURG. JOUR., Oct. 8, 1908.
[2] Feiss: Old Fracture Lower Epiphysis of Tibia, Corrected by Radical Operation. Surg., Gynec. and Obstet., June, 1909.

malleolus is prominent and gives an appearance of enlargement, and is lower than normal. There are a number of scars on the foot as a result of the former operation, one running down the inner side of the foot across tibial tendons. There is practically no power in tibials. Antero-posterior motion is fair. Lateral motion is restricted.

It was decided to manipulate the foot under an anesthetic and to correct the deformity. This was done; the foot was put up in plaster of Paris for two months, and was then given a brace. At that time the position was good and ankle motions were fair. The patient then went to his home.

The author did not think it advisable at that time to perform a more radical operation as the patient was still growing, but told the father that a more radical operation would probably be necessary. It is interesting to note in this case the small amount of pain and apparent disability which allowed the use of the leg a week after the injury.

THE HYGIENIC AND DIETETIC TREATMENT OF DELICATE CHILDREN BY THE CLASS METHOD. (ABSTRACT.) *

BY WM. R. P. EMERSON, M.D., BOSTON.

The problem of the treatment of delicate children is not a simple one. Its solution depends upon finding the causes of the condition. Heredity cannot always be blamed, because most delicate children were normal and healthy infants. If the child does not improve under our care, it is safe to say that we have not carried our investigations far enough. The belief that adequate causes can always be found by looking thoroughly into every detail of the child's life should mark the beginning of success in its treatment. Acting upon this supposition, the writer in the fall of 1908 collected into a class, fifteen of the weakest and most poorly nourished children from the four or five thousand patients coming to the Children's Department of the Boston Dispensary.

First. The past record of each child was considered carefully. A new and complete physical examination was made. The child's diet and home conditions were investigated, by giving each child a small record book to be brought in at the next visit. The child or parent was directed to keep a complete record of everything the child ate or drank for the following forty-eight hours. The time spent in sleep, out of doors, the exact number of minutes at meals, and such details as seemed necessary in each particular case, were considered.

Second. A social visitor was sent to the house, where she filled out a special card giving all the essential details in the child's home surroundings.

Third. Another card was filled out in relation to the child's diet, habits at meals, its likes and dislikes as regards the chief articles of food. Based upon the data thus obtained, a talk was given the class as a whole, explaining hygiene and diet and the open-air treatment. A few food values were given. Positive directions were given rather than negative ones. The child was encouraged to substitute cocoa for tea and coffee, fruit for sweets and simple puddings for rich pies and cake. Hesitation was felt in taking children into the class who had any functional or organic affections. It was found that such children gained as rapidly as the others. The class was held on Saturday mornings for one hour. As the child came in he was weighed and given a position in the class according to his gain or loss in weight. The weekly report books were examined. The visitor in charge of the patient made her report. Individual suggestions and directions were given. Where the child gained in weight little was said. If the child did not gain, a careful study was made to ascertain the reason, and almost without exception the reason was easily found. The other children and parents were sympathetic listeners, eager to know the cause of the child not gaining. The bringing out of practical points in this way constituted the most effective method of instruction. The analysis of the class records showed, as factors in their poor condition, adenoid growths in the nasopharynx, close relation to tuberculosis, frequent carious teeth, fickle likes and dislikes for food, rapid eating, the use of liquids to wash down the food, hygienic ignorance and lack of control on the part of the parents. It was found that if a child was absent for more than one week from the class he almost invariably lost in weight.

On June 1, there were six graduates from the class; that is, six children had gained normal weight and health. During the summer two more were added, making eight who had gained normal weight and health. The other seven were in excellent health and lacked but a few pounds or ounces of being normal in weight. Places were provided for all these children for summer outings and vacations; they were weighed again in the fall; their average monthly gain was less during the summer months than during the winter months when they were members of the class.

In the classes of 1908 and 1909 the average age on admission was eleven years. The average amount under weight was 12 lb. 3 oz. The largest amount under weight in any one child was 28¼ lb. The average weekly gain was 6.6 oz. The largest average weekly gain in any one child was 8 oz.

The following were found to be the most important points in the treatment of these children by the class method:

PARENTS.

In the class method the parents observe and learn; their intelligent co-operation in secured; where the parents cannot come to the class, it is necessary that a social worker act *in loco parentis*, else the child does not gain.

WINDOW TENTS.

Window tents were used by about one half of the class. They serve a double purpose by giving fresh air to the children at night and also during the rest period in the day time, without cooling off the rest of the house. The mothers often use them and are benefited. Tents help utilize rooms not otherwise suitable for sleeping purposes. In stormy weather, or when the mother is unable

* Read at a meeting of the New England Pediatric Society, May 21, 1910.

to go out, the child can get its airing by the use of the window tent. The whole cost of the tent need not exceed two dollars. Those using tents gained on an average of 3.3 lb. more than those who did not use them.

DIET AND THE PROPER MASTICATION OF FOOD.

The dietary was based upon the forty-eight-hour list of food. Cereals were added and the diet balanced. The child was encouraged to take from three to six glasses of milk daily. The total food value was increased from an average of 1,200 calories per day to an average of 2,000 calories per day. Every possible means was used to get the child to eat slowly, in two cases it being necessary for the parent to feed the child with a spoon for short periods.

SCHOOLS.

Children attended school regularly. In a few cases it was necessary to take them out for a short time. They always gained immediately upon being taken out of school. The writer believes that there should be open-air schools for all delicate children. The establishment of such schools would mark a great step in advance in preventive medicine.

CONCLUSIONS.

The class method is particularly well adapted to the proper treatment of delicate children. The spirit of competition, the "game" in it, has a powerful attraction to the child, aiding greatly in his management and control.

The steady gain in weight in children following directions furnishes a strong incentive to the parents and the children alike.

The class method makes the necessary instruction of the parents easy and effective.

The results obtained each week remove prejudices and fears and convince in a moment, as if by magic, where hours spent in arguments fail.

In the giving of instructions and directions to the parents and the children assembled together there is an enormous saving of time.

The class method furnishes the best training school for the social worker. She can here learn what instructions are to be carried out; what the object sought. She catches the spirit of the work and is enabled to relieve the physician of a large mass of detail for which he has neither the time nor the energy to perform, and for which the social worker is the one person especially qualified by sex and training to carry out.

Clinical Department.

THE PRESENCE OF AIR IN THE BLOOD VESSELS IN MEDICO-LEGAL AUTOPSIES.*

BY GEORGE L. WEST, M.D.,
Medical Examiner, Newton, Mass.

AIR may enter the circulation whenever a blood vessel, being opened by accident or design, makes a communication in the circulation between a negative pressure in the blood vessel and the positive pressure of the surrounding air. In the arteries, the blood pressure precludes this possibility. In the veins, however, the natural flow of the venous blood makes a tendency for the vessel, when cut off from the blood circuit, to empty itself toward the heart. This fact, especially when the vessel belongs to one of the great cavities of the body, creates the conditions of negative pressure within itself and, if the vessel is in communication with the air, bubbles may enter and are carried to the heart and lungs.

The chief interest in this subject to the medical examiner rests in those cases where air enters the venous sinuses of the uterus, where the detachment of the placenta in the pregnant uterus opens venous trunks having a portion of their course in the abdominal cavity and air enters through the dilated or patulous os. This condition occurs almost always as a result of the working of the professional abortionist.

In the case which I wish to report, the bubbles of air or gas did not come from any attempt at producing abortion and show at least the possibility of air appearing in the circulation through the uterine sinuses as a result of practices not connected with the production of abortion.

M. P., twenty-nine years old, a married woman, but at the time of death separated from her husband, the mother of three children, the youngest five years old, met by appointment on an evening in May her paramour and went with him to a lonely spot in the woods, where they indulged in sexual intercourse. Immediately after the act, the woman stood up, exclaimed, "Oh, my God, my head," and fell into her lover's arms unconscious. There was no convulsive effort. The man summoned a physician, who found the woman dead. The autopsy was made about twelve hours after death. Inspection of the body showed the presence of bits of dead twigs and pine needles pressed against the skin of the buttocks and a few pieces on the pubic region. About the vaginal orifice was a small quantity of dried dark-colored blood, and some fluid blood of dark color was seen on dilating the vagina. There was a slight tumefaction of the lower abdominal region. On opening the pulmonary artery *in situ*, there escaped blood thickly mixed with bubbles of air or gas. These bubbles were found also in the right side of the heart, which was dilated, and in the large venous vessels of the thorax and abdomen. The brain and meninges were normal. The uterus were found enlarged to a point about half way between the pubic bone and the umbilicus. It contained a perfectly formed male fetus nine inches long in unruptured membranes. The placenta was separated from the uterine walls in its lower segment over an area of about three or four square inches. The os was partially dilated.

The evidence showed that the lover had knowledge of the woman's condition and that she was anxious to rid herself of the fetus and had approached a physician, a man of good repute, who had refused to aid her in this direction. There was no evidence of instrumental attempt at producing abortion.

This woman, although separated from her husband, was not legally divorced and the act of sexual connection was an adulterous act and the

* Read before the Massachusetts Medico-Legal Society, Feb. 2, 1910.

man, if a partner in causing her death in this manner, was guilty of compounding a felony and liable, therefore, for manslaughter. No arrest was made.

It seemed to be a reasonable diagnosis to assign air-embolism as a cause of death, the air entering the partially dilated os and the exposed uterine sinuses during the muscular contractions incident to the sexual act.

Several years ago, Welch and Nuttall reported the discovery of the bacillus aerogenes capsulatus, which develops very rapidly in bodies after death, causing the appearance of bubbles of gas in the blood. The germ may be introduced into the body whenever a blood vessel is opened. Welch states that it is probable that many cases reported from the autopsy in which the patients are said to have died from the admission of air into the circulatory system have in reality died from some other cause, the gas produced by the bacillus having been mistaken for air.

It would appear, then, in such a case as this that the cause of death may not be definitely assigned without taking a culture from the blood, and that the medical examiner would have difficulty in defending his opinion of air-embolism as the cause of death in the face of a cross-examination by an attorney who had knowledge of the activity of the bacillus aerogenes capsulatus unless the medical examiner had previously fortified himself by making a culture from the blood of the deceased person to establish the absence of the bacillus.

Medical Progress.

REPORT ON OBSTETRICS.

BY ROBERT L. DE NORMANDIE, M.D.

Human Blood Serum in Hemophilia Neonatorum.
Chin Posterior Positions.
Pyelitis in Pregnancy.
Intramural Abscesses of the Puerperal Uterus.
Multiple Abscesses of the Puerperal Uterus.
Fibroma of the Uterus in Pregnancy and the Puerperium.
Action of Animal Extracts on Uterine Contractions.
Coagulation Time of the Blood in Phlebitis.
Jaundice in Four Successive Pregnancies with Fatal Jaundice in the Offspring.
Puerperal Sepsis Treated by Intravenous Injections of Magnesium Sulphate.
Eclampsia Treated by Continued Sugar-Water Instillation.
Incontinence of Urine after Labor.
Extraperitoneal Cesarean Section.
Pubiotomy.

NORMAL HUMAN BLOOD SERUM AS A CURATIVE AGENT IN HEMOPHILIA NEONATORUM.

Welch [1] reports nine cases of hemophilia neonatorum in which he has used normal human blood serum. He briefly mentions the fact that certain untoward symptoms may arise when animal serum is administered, and says further that death sometimes has followed direct transfusion of blood. The etiology in these cases is unknown, but in no case of this series was it traumatic. The bleeding took place from various parts and occurred in various amounts. The serum was given in varying dosage, depending upon the urgency of the case. Welch advises that at least 10 ccm. be given at the first injection and that it be repeated three times a day if the infant be bleeding but moderately. In severe cases it should be given every two hours, and in large quantities. He advises to begin the treatment at the first indication of bleeding, no matter how insignificant. The charts accompanying the paper are most striking and instructive. Should this method of treatment prove in other hands as certain as in the author's, it will be a great advance in the treatment of this condition. The method of obtaining the serum is very easy, and when one appreciates the great difficulties of doing a direct transfusion on newborn babies, and the comparatively few surgeons who can do it, it very readily is seen that this may become the accepted treatment for hemorrhagic disease of the newborn.

TREATMENT OF CHIN POSTERIOR POSITION.

Unterberger [2] reports two cases of chin posterior which he successfully delivered. Cases where the face is high and chin posterior he does not consider, but only those cases where the chin is posterior in the outlet of the pelvis and on the pelvic floor making other treatment except delivery impossible. Many excellent obstetricians he says advise at once perforation even of a living child in this condition. Unterberger does not agree to this. Forceps he advises if possible with the double application of Scanzoni. On two cases that he reports this maneuver failed, but he was able to rotate manually the chin from the posterior position anteriorly and then delivered the one case with forceps and the second case by Kristeller's method of expression. He favors in all cases where the chin is posterior, first rotating the head with the hand.

TREATMENT OF PYELITIS OF PREGNANCY BY LAVAGE.

Pilcher [3] reports six cases of pyelitis of pregnancy where he has catheterized the ureters and irrigated the pelvis of the kidneys with a 25% solution of argyrol. He reviews the causes previously mentioned for pyelitis. From his own studies he concludes that it is perfectly safe in cases where the symptoms are not severe to wait eight or ten days without attempting to catheterize the ureters, using the rules already formulated for diet and urinary antiseptics. From his observations he does not agree with the advice that the patient frequently assume a knee-chest posture. In the course of his cystoscopic examinations he found that more was to be gained by favoring drainage with the kidney on a higher level than the bladder. In cases of persistent temperature, with pain and pyuria, he advises passing a catheter to the pelvis of the affected kidney, draining it thoroughly and then to instill a dram of 25% argyrol. He agrees with the other writers that abortion or premature labor is seldom necessary. He is satisfied himself that the reaction of the urine in the pelvis of the kidney at least may be alkaline. This point depends upon the amount of retention there is in the pelvis.

INTRAMURAL ABSCESS OF THE PUERPERAL UTERUS.

Sampson [4] reports fully with diagrams and drawings four cases of intramural abscess of the puerperal uterus. He believes that it is of much more frequent occurrence than the number of reported cases would indicate. Sampson groups the cases into two distinct types: those in which the abscess or abscesses are the only result of the puerperal infection, and those in which the uterine condition is secondary in pathological importance. The first he reports as a clinical entity. The second is not, because of the greater importance of the other conditions present. Sampson believes that the apparent rarity of this condition is due to the fact that it is not diagnosed. The cause of this condition is a puerperal infection, and the patient gives a history of this infection which has not cleared up completely, that is, has become chronic. The subjective symptoms may be slight or severe, and on examination the uterus feels like a myomatous uterus, but the abscess masses are usually not so definite or as hard. A diagnosis is not always possible. In a patient who gives a history of chronic puerperal infection with an enlarged uterus which gives the impression of containing an indefinite myoma, a probable diagnosis of this condition can be made. If not operated upon, the abscess may rupture into any of the surrounding tissues or organs, but the possibility of its gradual absorption must be recognized. During the acute stage, operative procedures should be avoided if possible, all effort being directed to improve the patient's general resistance. After the acute stage has subsided, one must delay operative work until the patient no longer improves. Whether a hysterectomy is attempted or not depends upon the size and number of the abscesses present. Multiple incision and drainage of the abscess cavity may be made and a cure effected.

A CASE OF MULTIPLE ABSCESSES IN A PUERPERAL UTERUS.

Beyer [5] reports a case of multiple abscesses in a puerperal uterus. The patient had a normal delivery of twins, but during the labor she was found to have a fever. Four and a half weeks after delivery she was brought to Veit's clinic at Halle. Her temperature was slightly raised and pulse not increased in frequency. On the right side, almost level to the umbilicus, was a hard mass sensitive to pressure. Vaginal examination was not remarkable and did not clear the diagnosis. The patient was watched and, because of the mass remaining unchanged and painful, operation was advised. Laparotomy was done and a right-sided mass was found over a large surface, fluctuating and adherent to the abdominal wall. It was opened and found to be full of thick yellow, not foul-smelling pus. Cultures were taken from this pus. The mass proved to be an abscess around the perimetrium, with infiltration of the parametrium, which had started from an abscess in the uterus. Hysterectomy was done in order to obtain good drainage of the pus focus. The patient stood the operation badly, but gradually recovered and twelve weeks after operation was discharged well. Microscopic examination of the pus showed it to be a hemolytic though not virulent streptococcus. Microscopic examination of the uterine muscle showed it to be full of small abscesses, especially at the right tube. In these abscesses were found everywhere streptococci in large numbers.

NUTRITIONAL CHANGES IN FIBROMATA OF THE UTERUS INCIDENT TO PREGNANCY AND THE PUERPERIUM.

Fry [6] reviews the nutritional changes which occur in fibromata of the non-pregnant uterus and the physiological changes in fibromata complicating pregnancy. The characteristic points he says of the physiological changes complicating pregnancy are that the tumor increases in size, changes its position, undergoes alterations of shape and consistency, while it diminishes rapidly in volume and may disappear during the puerperium. The uterine structures are engorged with blood, but the fibroma receives an insufficient blood supply. The nutrient blood vessels do not enlarge to any appreciable extent, being surrounded by thick fibrous walls and deprived of the elastic coat. Changes in the arteries may exist to the extent of obliteration. The outside network of blood vessels shows increased vascularity, while the deeper parts of the tumor are found deprived of blood, and the result is degeneration. The increase in volume of the tumor is due more especially to the proliferation of the fibrous element, and especially to the serous infiltration. True growth of the tumor is relatively rare. The general tendency of the tumor is to become flattened and elongated during the pregnancy, but in the puerperium it often quickly assumes its original shape. Because of this alteration in shape of the tumor, many tumors which have blocked the pelvis during the early months of gestation and apparently present an insurmountable obstacle to delivery have often become flattered and elongated and allow delivery to take place. The pathological changes which take place are chiefly the type leading to necrosis and suppuration. Because of these nutritional changes, gangrene may follow. Pain and tenderness are marked clinical features. Besides the nutritional changes, complications arise which are due to mechanical causes such as incarceration within the true pelvis. Torsion of the pedicle may cause hemorrhage within the fibroma, and suppuration and softening with central necrosis often follows. Fry reports three cases which have not previously been reported. The first was a case where the tumor involved the body and fundus of the uterus, of the interstitial type. Labor progressed normally and rapidly and Fry let her deliver herself. Postpartum hemorrhage followed. Uterine packing was necessary, the patient apparently became septic and finally death followed. Autopsy showed a fibroma with a large abscess cavity having gangrenous walls and contents. The second case

was a suppurating fibroma during the puerperium, and supravaginal hysterectomy was successfully done. The third was a sloughing fibroma which recovered without operation. Fry concludes that the fatal cases presented difficult labors, and the frightful mortality when treated by delivery through the natural passages emphasizes the importance of early Porro-Cæsarean section. Cases of suppuration of fibroma after childbirth should be treated by prompt performance of supravaginal hysterectomy. A valuable lesson is taught in these cases by the disastrous results of delay and attempt to deliver by obstetric methods.

THE EFFECT OF ANIMAL EXTRACT UPON UTERINE CONTRACTIONS.

Ott and Scott [7] report briefly their results of injecting dried animal extracts into the jugular vein of animals on the uterine contraction. Of the thirteen extracts tried, those from the infundibular lobe of the hypophysis, brain, mammary gland, spleen, parathyroid and pancreas gave the most marked results upon the contraction of the uterus. The writers say that the infundibular extract has been used in post-partum hemorrhage and has stopped the bleeding in from three to four minutes. They stated that the contractions of the human uterus caused by this extract are more permanent than any other preparation, not excepting ergot. The preparation used was a 20% solution of the extract, of which 1 ccm. was given intramuscularly.

OBSERVATIONS ON COAGULATION TIME OF THE BLOOD IN A CASE OF PHLEGMASIA ALBA DOLENS AND ITS TREATMENT.

Jacobs [8] reports a case of phlegmasia alba dolens following a normal delivery. Both legs were involved when he saw the patient. Ten ccm. of blood were withdrawn for bacteriological examination, but the blood coagulated so rapidly that it could not be placed quickly enough in the culture tubes. The second blood culture was made the next day, and before the blood was withdrawn 2 ccm. of a 1.5% sterile solution of sodium citrate was put into the syringe in order to prevent coagulation. The result of this blood culture was negative. Because of this very rapid coagulation, Jacobs then decided to determine the coagulation time of the blood, with the result that it was found to be but forty-five seconds. Upon finding this fact, he gave the patient a dram of citric acid dissolved in a glass of water three times a day for the purpose of diminishing the coagulability of the blood and thereby preventing the further formation of thrombosis and possibly of hastening dissolution of the already formed thrombus. The improvement which followed was remarkable. In nine days the swelling was completely reduced in both limbs and the patient was allowed to sit up in bed. The coagulation time on the second day after citric acid was administered was one minute and fifteen seconds, and on the ninth day thirteen minutes and forty-five seconds. From this on she made a good convalescence. Jacobs describes the technic used for determining the coagulation time of the blood, which is the same as that employed in Sir A. E. Wright's laboratory. He closes his article by saying, "This case serves to illustrate very clearly the therapeutic effect that was obtained as the result of the administration of citric acid with the object of reducing the coagulability of the blood and thereby preventing further formation of thrombosis and hastening, as it did in this case, the dissolution of the already formed clot."

A CASE OF RECURRING JAUNDICE IN FOUR SUCCESSIVE PREGNANCIES WITH FATAL JAUNDICE IN THREE SUCCESSIVE INFANTS.

Rolleston [9] reports a case in which the patient had jaundice in four successive pregnancies and lost from jaundice three infants. The patient had in three pregnancies become jaundiced about the sixth month and subsequently suffered from much itching. She suffered from nausea, but no vomiting, and she had been constipated. The children were all born six weeks before term not jaundiced, but rapidly became so and died. The patient has never been jaundiced except when pregnant. In the fourth pregnancy she was treated with urotropin and salicylate of sodium from the second month, but at the sixth month she again became jaundiced with pruritus. There was no enlargement of the liver or spleen, and no note that the temperature or pulse was raised. At eight months premature labor came on and a boy was born without jaundice and none has since developed. In the first three children of this patient there was no autopsy. Rolleston has collected a short bibliography on this subject. In one family he found a case reported where, out of fifteen children, fourteen had been jaundiced and only four survived. Another case, eight cases of jaundice out of twelve pregnancies; four of these had been autopsied, but no lesions of the liver or bile ducts were found. In Rolleston's patient there was no evidence of syphilis. The only noticeable fact is that this condition has been recorded in families with large numbers of pregnancies. Rolleston feels that the recurring jaundice is probably toxic. This condition of recurring jaundice in pregnancy in the mother with fatal jaundice in the offspring is, as far as he knows, the first recorded. He feels that the most reasonable method of treatment is to treat the mother with biliary and intestinal antiseptics, and to regulate the diet and to prevent constipation.

A CASE OF PUERPERAL BACTEREMIA TREATED BY INTRAVENOUS INJECTION OF MAGNESIUM SULPHATE.

Huggins [10] makes a preliminary report of his use of magnesium sulphate in the treatment of puerperal infections. He says that experiments both in animals and in humans have demonstrated that the administration of this salt intravenously is safe and is a valuable therapeutic agent. When indicated, the intravenous injection is supplemented by a continuous intra-uterine irrigation of a solution of magnesium sulphate. He reports a case of

a patient who gave a history of fever, sweats and chills, covering a period of ten days, after an abortion at the second month. Blood culture showed a streptococcus in pure culture at the end of forty-eight hours. The treatment then given was a solution of magnesium sulphate 25 gr. in 500 ccm. of normal salt solution intravenously. This solution was allowed to run into the vein slowly, occupying about forty-five minutes. Following the administration of the magnesium sulphate, the temperature, which had been running from 102–104, and pulse from 115–120, rose to 104 and then fell to 97, where it remained for six hours. The pulse became somewhat slower and improved in quality. Three days later the same solution was given a second time and the temperature rose, followed quickly by a sharp fall. From then on there was a gradual improvement in the condition of the patient in every way, and eight days after the patient was admitted to the hospital her temperature dropped to 99. She then developed a phlebitis with marked edema and swelling of the leg. This phlebitis was later incised and drained, but no pus obtained, but the patient was a great deal relieved by the operation. Fifteen days after the patient entered the hospital the blood culture showed no streptococci in the blood. She finally made a good recovery and was discharged from the hospital well.

TREATMENT OF ECLAMPSIA BY CONTINUED SUGAR WATER INSTILLATION.

Jacobson [11] writes a short review of eclampsia and then says that in his opinion uremia or eclampsia is caused by retention in the blood of the salts, principally the sodium chloride which the damaged kidneys are unable to throw out in sufficient quantity with the urine. By the retention of these salts, the molecular concentration of the blood and at the same time the specific gravity of the blood is raised. In order to reduce this molecular concentration, two methods seem to be favorable, — starving the patient and diluting the patient's blood by adding water. Jacobson withholds all food from eclamptics for three days except water. The usual physiological saline solution he rejects as dangerous and illogical, and for that reason he has given up its use and decided upon a solution of sugar in water. The two cases he reports which were treated by this method both made a good recovery, and observation of the specific gravity of the patient's blood showed that it dropped from 1,060 to 1,052. The two cases are characteristic cases of eclampsia, but from these two cases, of course, it is impossible to say whether the sugar solution had any real effect or not on the patients.

INCONTINENCE OF URINE FOLLOWING LABOR.
